EDITION

BROCK BIOLOGY OF MICROORGANISMS

SIXTEENTH EDITION

Madigan • Bender • Buckley • Sattley • Stahl

Brief Contents

UNIT 1 The Foundations of Microbiology	CHAPTER 1 CHAPTER 2 CHAPTER 3 CHAPTER 4 CHAPTER 5	The Microbial World 37 Microbial Cell Structure and Function 74 Microbial Metabolism 111 Microbial Growth and Its Control 144 Viruses and Their Multiplication 184
UNIT 2 Molecular Biology and Genetics	CHAPTER 6 CHAPTER 7 CHAPTER 8 CHAPTER 9	Molecular Information Flow and Protein Processing 201 Microbial Regulatory Systems 236 Molecular Aspects of Microbial Growth 270 Genetics of <i>Bacteria</i> and <i>Archaea</i> 297
UNIT 3 Genomics, Synthetic Biology, and Evolution	CHAPTER 10 CHAPTER 11 CHAPTER 12 CHAPTER 13	Microbial Genomics and Other Omics 328 Viral Genomics and Diversity 361 Biotechnology and Synthetic Biology 390 Microbial Evolution and Genome Dynamics 428
UNIT 4 Microbial Diversity	CHAPTER 14 CHAPTER 15 CHAPTER 16 CHAPTER 17 CHAPTER 18	Metabolic Diversity of Microorganisms 460 Ecological Diversity of <i>Bacteria</i> 514 Phylogenetic Diversity of <i>Bacteria</i> 555 Diversity of <i>Archaea</i> 592 Diversity of Microbial <i>Eukarya</i> 621
UNIT 5 Microbial Ecology and Environmental Microbiology	CHAPTER 19 CHAPTER 20 CHAPTER 21 CHAPTER 22 CHAPTER 23	Taking the Measure of Microbial Systems 648 Microbial Ecosystems 687 Nutrient Cycles 729 Microbiology of the Built Environment 754 Microbial Symbioses with Microbes, Plants, and Animals 780
UNIT 6 Microbe–Human Interactions and the Immune System	CHAPTER 24 CHAPTER 25 CHAPTER 26 CHAPTER 27 CHAPTER 28	Microbial Symbioses with Humans 819 Microbial Infection and Pathogenesis 850 Innate Immunity: Broadly Specific Host Defenses 868 Adaptive Immunity: Highly Specific Host Defenses 892 Immune Disorders and Antimicrobial Therapy 919
UNIT 7 Infectious Diseases	CHAPTER 29 CHAPTER 30 CHAPTER 31 CHAPTER 32 CHAPTER 33 CHAPTER 34	Diagnosing Infectious Diseases 943 Epidemiology and Public Health 965 Person-to-Person Bacterial and Viral Diseases 986 Vectorborne and Soilborne Bacterial and Viral Diseases 1019 Waterborne and Foodborne Bacterial and Viral Diseases 1037 Eukaryotic Pathogens: Fungi, Protozoa, and Helminths 1059

Authoritative. Accurate. Accessible.

Brock Biology of Microorganisms is the leading microbiology text for majors, setting the standard for impeccable scholarship, accuracy, a visually stunning art program, and the use of cutting-edge research to illustrate basic concepts.

Making Connections Across

UPDATED! Each chapter is carefully cross-referenced to connect students with related material found earlier (◀) or later (▶) in the book.

I • Bacterial Cell Division

Prokaryotic cell division is preceded by chromosome replication and the synthesis of new cell wall material in a way that defines cell shape. Cell division is orchestrated in a carefully controlled fashion by protein complexes whose activities can be visualized by powerful light microscopic techniques.

Most cells divide by binary fission (◀ Section 4.6 and Figure 4.8), and this process occurs in a defined series of steps such that each daughter cell obtains a copy of the genome. During the division cycle, the cell must also produce new peptidoglycan and cytoskeleton elements to prevent bursting from osmotic forces. This cytoskeleton gives the cell its distinct morphology (◀ Figure 1.8). To successfully orchestrate all of these events, various regulatory cascades are put into play. In this first part of the chapter we focus on the molecular mechanisms employed by two well-studied gram-negative bacteria, *Escherichia coli* and *Caulobacter crescentus*, and introduce advanced microscopic techniques that have revealed the major molecular events that underlie cell division and cell morphology.

NEW! Key Concept statements at the start of each key topic of a chapter give students a big-picture view of the content to come before they dive in and immerse themselves in the details.

Figure 4.8 Binary fission in a rod-shaped bacterium. Cell numbers (and all components of the cells) double every generation.

Figure 1.8 Cell morphologies. Beside each drawing is a phase-contrast photomicrograph of cells showing that morphology. Coccus (cell diameter in photomicrograph, 1.5 μm); rod (1 μm); spirillum (1 μm); spirochete (0.25 μm); budding (1.2 μm); filamentous (0.8 μm). All photomicrographs are of species of *Bacteria*. Not all of these morphologies are known among the *Archaea*, but cocci, rods, and spirilla are common.

Concepts in Microbiology

NEW! Marginal annotations highlight some of the best material available for instructors to assign in Mastering Microbiology, guiding students along their journey with insightful materials that support and strengthen the learning experience.

Mastering Microbiology

Art Activity:

somatotropin

Figure 10.29 The components of systems biology. (a) The results of various “omics” analyses are combined and successively integrated into higher-level views of the entire biology of a pure culture, such as (b) that of the green sulfur bacterium *Chlorobium*; or of a mixed microbial community, such as (c) that of phototrophic sulfur bacteria obtained from a lake; or of a single cell isolated from a microbial community (see Figure 10.30).

Genomics, and the various “omics” it has spawned, is woven into every chapter of the text, providing students with concrete examples of how powerful tools have allowed microbiologists to probe deeper and farther into the microbial world than ever before.

Cutting-Edge Content

MICROBIOLOGYNOW

When Antibiotics Fail, Bacteriophage Therapy to the Rescue

Acquiring an antibiotic-resistant infection or “superbug” is one of medicine’s biggest nightmares. What can medical practitioners do to treat the patient? Besides drugs, viruses known as bacteriophages have been recruited to specifically target and kill bacteria.

Despite microbiologists’ tinkering with using bacteriophages as antimicrobials for decades, their actual application in medicine has been minimal. However, the emergence of antibiotic resistance has led to renewed focus on using these tiny microbes as therapeutic agents. The photo above shows Ella Balasa (right side of photo), a microbiologist who has cystic fibrosis. Cystic fibrosis is a genetic disease that results in a buildup of thick mucus in the lungs. This mucus allows bacteria to flourish in the lungs, which results in infections and subsequent lung damage that can be fatal. Ella had been treated numerous times with strong antibiotics specific for a respiratory infection caused by the bacterial pathogen *Pseudomonas aeruginosa*, but the microbial cells had become unresponsive to the drugs. At the time of this photo,

the recurrent infection had decreased her lung function to the point where she required constant supplemental oxygen.

As an alternative treatment route, Dr. Benjamin Chan (on the left) took mucus from Ella’s lungs infected with *P. aeruginosa* and isolated a bacteriophage that specifically killed the pathogen (see zones of clearing on Petri plate). This bacteriophage was propagated and then poured into a device so that Ella could inhale the therapy. The result of her treatment? Amazingly, the bacteriophage therapy along with a mixture of antibiotics resulted in the infection clearing a few weeks later!

While bacteriophage therapy is highly specific and the ability of the pathogen to become resistant to viral infection, there are success stories that illustrate the future of phage therapy when all other options fail.

Source: Kortright, K.E., B.K. Chan, J. Phage therapy: A renewed approach to treating bacteria. *Cell Host Microbe* 28(2): 211–221 (2020).

NEW! Thirty-four Microbiology Now chapter opening vignettes were composed for this edition, each designed to introduce a chapter’s theme through a recent discovery in the field of microbiology. These exciting accounts will draw students into the chapter and show how the chapter content connects with real-world problems.

NEW! Several new Explore the Microbial World features provide fascinating stories that highlight how important chapter concepts have evolved from research in the microbial world.

Explore the Microbial World

Pattern Recognition Receptors of Hydrothermal Vent Tube Worms Facilitate Endosymbiosis

Invertebrates and plants lack adaptive immunity but have a well-developed innate immune response to a wide variety of pathogens. As discussed in Section 26.6, virtually all multicellular organisms respond to pathogen invasion by recognizing signature molecules found on pathogen surfaces. These molecules contain conserved, repetitive structures called pathogen-associated molecular patterns (PAMPs) that include molecules such as the lipopolysaccharide (LPS) and flagellin of gram-negative bacteria, the peptidoglycan of gram-positive bacteria, and the

mutualistic partnership rather than a confrontation between a host and the bacteria that colonize it. As we learned in Chapter 23, a wide variety of plants and animals maintain symbiotic relationships with microorganisms. There we discussed the association of tube worms that develop near hydrothermal vents in the deep sea with autotrophic, sulfur-oxidizing bacteria (SOB) that inhabit their trophosome, a spongy internal organ that comprises most of the volume of the 1- to 2-m-long worms (Figure 1). These SOB form an endosymbiosis with the worms in which the bacteria provide all organic carbon requirements for their animal host in exchange for a steady supply of essential metabolites, in particular H_2S , O_2 , and CO_2 . H_2S is the energy source for the SOB; they oxidize it to S^0 and then SO_4^{2-} and respire the electrons to generate a proton motive force that drives ATP synthesis. Oxygen (O_2) is required as a terminal acceptor of electrons that have traversed the electron transport chain. CO_2 is the carbon source and is incorporated into bacterial cell material by way of

the Calvin cycle, the major means of autotrophy in chemolithotrophic bacteria.

This fascinating association raises the question of how it is established. Specifically, how does the tube worm populate its trophosome with SOB to the exclusion of other, potentially pathogenic, bacteria? The answer appears to be closely linked to MAMPs associated with the endosymbiotic SOB. Although host PRRs are typically used to recognize and eliminate pathogens, the study of tube worms and other animals that harbor endosymbiotic microbes shows a broader functionality for PRRs in that they can also interact beneficially with MAMPs to selectively populate a host with nonpathogenic symbionts.

The tube worm trophosome contains a large number of specialized host immune cells called bacteriocytes, and it is within these cells that the bacterial symbionts take up residence. The tube-worm bacteriocytes express high levels of PRRs that recognize MAMPs, such as specific cell surface lipoproteins associated with SOB. This positive interaction locates the bacteria to the trophosome and, with a steady supply of simple nutrients from the hydrothermal vent system delivered by blood circulating in the worm, stimulates colonization and growth of the symbionts in their animal host.

As this example illustrates, in addition to providing a rapid response to pathogen challenge, innate immune mechanisms—specifically, the interaction of PRRs with MAMPs—may also serve the primary role in governing host–symbiont interactions and the establishment of endosymbiotic relationships.

Given the critical role innate immune mechanisms play in maintaining the animal–bacterial symbiosis within the tube-worm trophosome, it is likely that similar tightly choreographed molecular mechanisms constitute a host–microbe “dialogue” that helps to maintain balanced communities of beneficial microbiota in virtually all animals, including humans.

double-stranded RNA of certain viruses. The term *microbe-associated molecular pattern*, or MAMP, is also commonly used to describe signature molecules found on microorganisms. However, “MAMP” is a broader term than “PAMP” because it includes components found on microorganisms that are not pathogenic.

Unlike PAMPs, which are exploited specifically for innate defense against pathogens, MAMPs found on nonpathogenic bacteria can serve an entirely different purpose—that of facilitating, through host pattern recognition receptors (PRRs), a

Figure 1 Hydrothermal vent tube worms harboring endosymbiotic sulfur-oxidizing bacteria. Top: A “black smoker” hydrothermal vent community containing several tube worms that obtain organic carbon from sulfur-oxidizing chemolithotrophic bacteria (SOB) living within them. Bottom: A close-up view of tube worms; each worm is 1–2 m long. The red area on the top of each worm, called the plume, is where O_2 and H_2S are taken in to be fed to the worm’s SOB endosymbionts residing in the trophosome.

NEW! A section on immunotherapy highlights exciting advancements in the use of genetic engineering and molecular immunology to treat cancer.

NEW! The chapter on the human microbiome now includes a new section on the human virome, describing how metagenomics is aiding the discovery and isolation of many new viruses. Extensive coverage is provided of the impact of early life events on the development of the newborn gut microbiome and of recent successes in probiotic therapy for preventing newborn intestinal diseases.

Empower Each Learner

NEW! Dynamic Study Modules help students study course topics by adapting to their performance in real time. Students build the confidence they need to deepen their understanding, participate meaningfully, and perform better—in and out of class. Available on smartphones, tablets, and computers.

Mastering is so much more than homework. The **Pearson Study Area** allows students to access multiple study tools in one place. They don't need to search Google to find study tools that align with their course materials. Students have access to practice quizzes, videos and animations, vocabulary tools, and more.

with Mastering Microbiology

Get students engaged with content by assigning a variety of questions in Mastering Microbiology. These include:

- Reading Questions
- Art-Based Activities
- Coaching Activities and more

Interactive Microbiology is a dynamic suite of interactive tutorials and animations that teach key microbiology concepts including Operons, Biofilms and Quorum Sensing, Complement, Human Microbiota, and Antibiotic Resistance. Interactive Microbiology actively engages students with each topic, enabling them to learn from manipulating variables, predicting outcomes, and answering formative and summative assessment questions. Each tutorial presents the concept within a real healthcare scenario in order to emphasize problem solving and interest students from the beginning.

Pearson eText: A Whole New Reading Experience

Figure 9.4 Screening for nutritional auxotrophs.

The replica-plating method can be used for the detection of nutritional mutants. Colonies from the master plate are transferred using a sterile toothpick to a gridded plate containing different media for selection. The colonies not appearing on the selective medium are labeled as auxotrophs. The selective medium lacked one nutrient (the amino acid leucine) present in the master plate. Therefore, the colonies on the complete medium plate that are not represented on the selective medium plate are leucine auxotrophs (Leu⁻).

Derek J. Fisher

A mutant strain with an additional nutritional requirement above that of the **wild type or parental strain** from which it was derived is called an **auxotroph** (Table 9.1), and the strain from which an auxotroph originates is called a **prototroph**. For instance, mutants of *E. coli* with His⁻ and Mal⁻ (Figure 9.2) phenotypes are histidine and maltose auxotrophs, respectively, while the parental His⁺ and Mal⁺ strains from which the auxotrophs were derived are the prototrophs of such strains. As described earlier, many different mutations can lead to a strain showing a His⁻ or Mal⁻ phenotype, and thus an initial step in characterizing the genetics of a metabolic pathway (such as histidine biosynthesis and maltose catabolism) would be the isolation of several His⁻ or Mal⁻ strains followed by their comparative genetic analyses (Figure 9.2). This comparative analysis process, called **complementation**, is discussed in Section 9.5.

NEW! Pearson eText is a simple-to-use, mobile-optimized, and personalized reading experience available within Mastering. It allows students to easily highlight, take notes, and review key vocabulary all in one place—even when off-line. Seamlessly integrated videos and other rich media engage students and give them access to the help they need, when they need it.

Pearson eText App now enables students to access their eText and associated study tools and notebook off-line. All they need to do is download the app!

Figure 19.14 Catalyzed reporter deposition FISH (CARD-FISH) labeling of Archaea.

Archaeal cells in this preparation fluoresce intensely (green) relative to DAPI-stained cells (blue).

Besides detecting mRNA, CARD-FISH is also useful in phylogenetic studies of microbes that may be growing very slowly, such as organisms inhabiting the open oceans where cold temperatures and low nutrient concentrations limit growth rates (Figure 19.14). Because such cells have few ribosomes compared with more actively growing cells, **standard FISH often yields only a weak signal.**

Check Your Understanding

- What structure in the cell is the target for fluorescent probes in phylogenetic FISH?
- FISH and CARD-FISH can be used to reveal different things about cells in nature. Explain.
- Compare the utility of CARD-FISH versus BONCAT-FISH for evaluating cellular activity.

About the Authors

Michael T. Madigan received his B.S. in Biology and Education from Wisconsin State University–Stevens Point (1971) and his M.S. (1974) and Ph.D. (1976) in Bacteriology from the University of Wisconsin–Madison in the laboratory of Thomas Brock. Following a postdoc at Indiana University with Howard Gest, Mike moved to Southern Illinois University Carbondale, where he taught courses in introductory microbiology and bacterial diversity as a professor of microbiology for 33 years. In 1988 Mike was selected as the Outstanding Teacher in the College of Science and in 1993, the Outstanding Researcher. In 2001 he received the SIUC Outstanding Scholar Award and Distinguished Professor title. In 2003 Mike received the Carski Award for Distinguished Undergraduate Teaching from the American Society for Microbiology (ASM), and he is an elected Fellow of the American Academy of Microbiology (ASM) and the American Association for the Advancement of Science (AAAS). He has also been recognized by the American Red Cross as a major volunteer blood donor for the 24 gallons of blood he has donated since 1967. Mike’s research is focused on phototrophic bacteria that inhabit extreme environments, and for the past 20 years his emphasis has been Antarctic microbiology. Mike has co-edited a major treatise on phototrophic bacteria and served for 10 years as chief editor of the journal *Archives of Microbiology*. He currently serves on the editorial board of the journals *Environmental Microbiology* and *Antonie van Leeuwenhoek*. Mike’s other interests include forestry, swimming, reading, and caring for his dogs and horses. He lives on a small farm near a quiet lake with his wife, Nancy, three dogs (Kato, Nut, and Merlyn), and three horses (Eddie, Georgie, and Roscoe).

Kelly S. Bender received her B.S. in Biology from Southeast Missouri State University (1999) and her Ph.D. (2003) in Molecular Biology, Microbiology, and Biochemistry from Southern Illinois University Carbondale. Her dissertation research focused on the genetics of perchlorate-reducing bacteria. During her postdoctoral fellowship, Kelly worked on the genetic regulation of sulfate-reducing bacteria in the laboratory of Judy Wall at the University of Missouri–Columbia. She also completed a transatlantic biotechnology fellowship at Uppsala University in Sweden researching regulatory small RNAs in bacteria. In 2006, Kelly returned to her alma mater, Southern Illinois University Carbondale, as an Assistant Professor in the Department of Microbiology and in 2012 was tenured and promoted to Associate Professor. She has served as Chair of the SIUC Department of Microbiology since 2018. Her lab studies a range of topics including regulation in sulfate-reducing bacteria, the microbial community dynamics of sites impacted by acid mine drainage, and diversity of phototrophic heliobacteria. Kelly teaches courses in introductory microbiology and microbial diversity, has served on numerous federal grant review panels, and is an active member of the American Society for Microbiology (ASM). Her other interests include spending time with her daughter, Violet, and husband, Dick.

Daniel H. Buckley is a Professor at Cornell University in the School of Integrative Plant Science and the Department of Microbiology. He earned his B.S. in Microbiology (1994) at the University of Rochester and his Ph.D. in Microbiology (2000) at Michigan State University. His graduate research in the laboratory of Thomas M. Schmidt explored environmental factors that influence microbial diversity in soils. Dan then received a National Science Foundation Postdoctoral Fellowship to work with Pieter T. Visscher, University of Connecticut, investigating linkages between microbial diversity and biogeochemistry within microbial mats and stromatolites. Dan moved to Cornell in 2003 where he investigates the ecology and evolution of the diverse microorganisms that live in soils. He has taught both introductory and advanced courses in microbiology, microbial diversity, and microbial genomics. He received a National Science Foundation Faculty Early Career Development (CAREER) award in 2005 for excellence in integrating research and education, and served as Co-Director of the MBL Microbial Diversity summer course in Woods Hole, Massachusetts (2009–2013). He currently serves on the editorial boards of *Applied and Environmental Microbiology* and *Environmental Microbiology*. Dan lives in Ithaca, New York, with his wife, Merry, and sons, Finn and Colin.

W. Matthew Sattley received his B.A. in Biology in 1998 from Blackburn College (Illinois) and his Ph.D. (2006) in Molecular Biology, Microbiology, and Biochemistry from Southern Illinois University Carbondale. His graduate studies focused on the microbiology of sulfur cycling and other biogeochemical processes in permanently ice-covered lakes of Antarctica. In his postdoctoral research at Washington University in Saint Louis, he studied the physiology and genomics of anoxygenic phototrophic bacteria in Robert Blankenship's laboratory. Matt then accepted a faculty appointment to the Department of Biology at MidAmerica Nazarene University (Kansas), where he supervised undergraduate research and taught courses in microbiology, environmental science, and cell biology. In 2010, Matt transitioned to the Division of Natural Sciences at Indiana Wesleyan University (IWU), where he is a Professor of Biology and has served as the Director of the Hodson Research Institute, a faculty-led summer research program for undergraduate students in the Natural Sciences. Matt's research group investigates the ecology, diversity, and genomics of bacteria that inhabit extreme environments, and in 2017, he was the recipient of IWU's Outstanding Scholarship Award. Matt is a member of the American Society for Microbiology (including its Indiana Branch) and the Indiana Academy of Science. Matt lives in Marion, Indiana, with his wife, Ann, and sons, Josiah and Samuel. Outside of teaching and research, Matt enjoys playing drums, reading, motorcycling, and baseball.

David A. Stahl received his B.S. degree in Microbiology from the University of Washington, Seattle, and completed graduate studies in microbial phylogeny and evolution with Carl Woese in the Department of Microbiology at the University of Illinois at Urbana-Champaign. Subsequent work as a postdoctoral fellow with Norman Pace, then at the National Jewish Hospital in Colorado, involved early applications of 16S rRNA-based sequence analysis to the study of natural microbial communities. In 1984 Dave joined the faculty at the University of Illinois with appointments in Veterinary Medicine, Microbiology, and Civil Engineering. In 1994 he moved to the Department of Civil Engineering at Northwestern University, and in 2000 returned to the University of Washington as professor in the Departments of Civil and Environmental Engineering and Microbiology. Dave is known for his work in microbial evolution, ecology, and systematics, and received the 1999 Bergey Award and the 2006 ASM Procter & Gamble Award in Applied and Environmental Microbiology. Dave is an elected fellow of the American Academy of Microbiology and a member of the National Academy of Engineering. His main research interests surround the biogeochemistry of nitrogen and sulfur and the microbial communities that sustain the associated nutrient cycles. His laboratory was the first to culture ammonia-oxidizing *Archaea*, a group believed to be the key mediators of this process in the nitrogen cycle. Dave has taught several courses in environmental microbiology, was one of the founding editors of the journal *Environmental Microbiology*, and has served on many advisory committees. Outside the lab, Dave enjoys hiking, bicycling, spending time with family, reading a good science fiction book, and—with his wife, Lin—renovating an old farmhouse on Bainbridge Island.

Dedications

Michael T. Madigan

dedicates this book to the 10^{31} (more or less) microbial cells on and within Earth that maintain our planet in a habitable state. Keep up the good work, guys.

Kelly S. Bender

dedicates this book to the memory of her grandmother, Alberta, whose biggest regret in life was not being able to attend school past the fifth grade.

Daniel H. Buckley

dedicates this book to his father, Ron, who taught me ingenuity and persistence.

W. Matthew Sattley

dedicates this book to the memory of his father, Steven, and to his mother, Patrice, for demonstrating the benefits of working hard and seeking knowledge.

David A. Stahl

dedicates this book to his wife, Lin. My love, and one that helps me keep the important things in perspective.

This page is intentionally left blank

Preface

Welcome to the best learning resource in microbiology education today: the visually stunning 16th Edition of *Brock Biology of Microorganisms* (BBOM). The 16th Edition is the most student-friendly and accessible edition yet and presents the most exciting and recent picture of the science of microbiology available today. For three generations, both students and instructors alike have praised the accuracy, authority, consistency, and teachability of BBOM for exploring the principles of microbiology in a readable, connected, and visually appealing way.

Both students and instructors will benefit from at least four important strengths of the 16th Edition: (1) our approach of using cutting-edge research to solidify basic concepts; (2) the seamless integration of molecular and ecological microbiology with coverage of evolution, diversity, the immune system, and infectious diseases; (3) the spectacular art program complemented with striking and compelling photos; and (4) the wide assortment of teaching and learning tools that accompany the book itself. With an extremely strong author team that employs experts in each major theme, BBOM 16th Edition leads the way in presenting the essential principles of microbiology that students need to master today.

What's New in the 16th Edition?

The 16th Edition guides students through the six major themes of microbiology as outlined by the American Society for Microbiology Conference on Undergraduate Education (ASMCUE): Evolution, Cell Structure and Function, Metabolic Pathways, Information Flow and Genetics, Microbial Systems, and the Impact of Microorganisms. With new and revised artwork complemented by over 60 new photos, BBOM 16th Edition (16e) presents microbiology as the visual science it is. Thirty-four new MicrobiologyNow chapter-opening vignettes were composed for this edition, each designed to introduce a chapter's theme through a recent discovery in the field of microbiology. These exciting accounts will naturally draw students into the chapter and show how the chapter's content connects with real-world problems. Several new Explore the Microbial World features were also developed for this edition, each designed to give students a feel for exciting special topics in microbiology and to fuel their scientific curiosity.

Genomics, and all of the various "omics" it has spawned, support content in every chapter of BBOM 16e, reflecting the reality of how omics has transformed all of biology, especially microbiology. The result is a robust and modern treatment of microbiology that guides students through the maze of omics with concrete examples of how these powerful tools have allowed microbiologists to probe deeper and farther into the microbial world than ever before.

To reinforce the learning experience, the 16e debuts a new pedagogical aid called Key Concepts. These brief summaries of each chapter part are written in clear and straightforward language that give students a heads-up as to what is coming in the following sections. Complementing

the Key Concepts, each numbered section is summarized in the chapter review and accompanied by a review question that links concept review with concept mastery.

BBOM 16e is supported by Mastering Microbiology, Pearson's online homework, tutorial, and assessment system that assists students in pacing their learning and keeps instructors current on class performance. Mastering Microbiology includes a new feature, Dynamic Study Modules, which adapt to the student's performance in real time to help each student's study of course topics. Students build the confidence they need to deepen their understanding, participate meaningfully, and perform better in and out of class. Other highlights include chapter-specific reading quizzes, MicroLab Tutorials, MicrobiologyNow coaching activities, Clinical Case and MicroCareer coaching activities, animation quizzes, MCAT Prep questions, and many additional study and assessment tools. Collectively, the content and presentation of BBOM 16e, coupled with the powerful learning tools of Mastering Microbiology, create an unparalleled educational experience in microbiology.

Revision Highlights

UNIT 1 The Foundations of Microbiology

Chapter 1

- The microbial world is introduced in an exciting and novel way by weaving together core concepts in microbiology with the historical events that led to their discovery. The foundations of microbiology are revealed through introductions to microscopy, laboratory cultivation, microbial evolution, and the molecular principles that unify all life.
- Some highlights: Vibrant new images help connect students with the diverse and numerous ways in which microbiology impacts our world. Coverage of cell size and morphology is introduced here rather than in Chapter 2 in order to draw students into the microscopic world early on and introduce them to actual microbes and their properties.

Chapter 2

- In the microbial world, cellular structures are tightly linked to cell functions, and Chapter 2 offers a complete guide to the features that define and differentiate microbial cells and their functions. Updated coverage of nutrient transport here rather than in the growth chapter places this critical cellular activity firmly within the context of the cell envelope.
- Some highlights: Electron cryotomography has provided new insight into cell biology and is incorporated in new views of peptidoglycan structure, S-layers, and diversity in cell envelope organization. Vivid new illustrations developed from cutting-edge

microscopic images of the flagellum, the archaellum, and the rotating proteins that confer gliding motility provide a fresh new look at how these structures move prokaryotic cells about their environments.

Chapter 3

- This chapter remains focused on the fundamentals of metabolism and has been revised to simplify metabolic concepts and emphasize the modularity of metabolism. The chapter starts with the essential principles and then provides examples of their application while guiding the student through the major metabolic processes that define microbial life.
- Some highlights: New art provides greater clarity and realism in understanding electron transport reactions, making this process easier to understand and easier to teach. Modularity of metabolism and the importance of the proton motive force receive greater emphasis by providing simple examples of chemolithotrophy and phototrophy to reinforce the student's understanding of energy conservation as a unifying concept in biology. Updates to fermentation clarify and distinguish this process from anaerobic respiration, and an overview of autotrophy and nitrogen fixation emphasize the connectivity between anabolic and catabolic processes in the cell.

Chapter 4

- This chapter on microbial growth and its control moves up one slot from the previous edition to better prepare students for dealing with concepts in molecular biology and genetics where microbial growth plays a central role.
- Some highlights: The essentials of microbial nutrition and laboratory culture are introduced here with a segue to counting methods and quantitative aspects of microbial growth. The dynamics of microbial growth are emphasized with exciting new coverage of the biofilm mode of growth and alternatives to binary fission. The latter includes organisms that display budding division such as *Caulobacter*—the prime model for developmental studies of bacteria—and bacteria that grow by hyphal extensions characteristic of filamentous bacteria such as *Streptomyces*, a major producer of antibiotics.

Chapter 5

- This introduction to virology moves up from its position in Unit 2 in the previous edition to round out the foundations of microbiology theme of Unit 1. This move gives earlier visibility to the importance of viruses as microbes, clearly explains how they differ from cells, and lays the necessary groundwork for dealing with the genetics, genomics, and molecular biology that follows in Unit 2.
- Some highlights: Emphasis remains on the basic principles of virology including how viruses and cells can be viewed as both similar and different and how methods for replicating viruses resemble those for growing cells. Bacteriophage T4 is used as a model lytic virus, and coverage of eukaryotic viruses is expanded beyond just animal viruses to include some major viruses of plants. This highly visual chapter is embellished with over a dozen new photos of exciting, newly discovered viruses along with supporting art that underscores the fundamentals of virology.

UNIT 2 Molecular Biology and Genetics

Chapter 6

- Moved forward two slots from its position in the previous edition to better fit as the kick-off to Unit 2, this chapter lays the necessary groundwork in molecular biology for tackling microbial genetics and genomics and the fast-moving fields of synthetic biology, molecular microbial ecology and diversity, the human microbiome, and diagnostic microbiology.
- Some highlights: Reorganized coverage of DNA supercoiling precedes new and more realistic depictions of the seminal processes of replication, transcription, and translation. New coverage of transcriptional processes in *Archaea* and their relationship to those in *Eukarya* and updated coverage of protein secretion round out this essential primer in microbe molecular biology that every student needs to master.

Chapter 7

- Because microbes must coordinate cellular processes to optimize their chances for survival and reproduction, Chapter 7 is central to Unit 2 in describing how prokaryotic cells control the seminal processes of replication, transcription, and translation. Microbial regulatory systems are highly diverse and sometimes tiered, but an appreciation for how control systems work is key to understanding metabolic diversity, pathogenesis, and synthetic biology.
- Some highlights: Reorganized and expanded coverage of gene expression in *Bacteria* and *Archaea* including activation and repression/derepression as well as chemotaxis and global controls. New coverage of two-component systems for regulating nitrogen assimilation and updated coverage of the phosphate regulon, heat shock response, and riboswitch activity exemplify the comprehensive nature of this chapter.

Chapter 8

- This chapter continues the molecular theme of Unit 2 by building on the major topics of Chapters 4, 6, and 7 in the context of the mechanisms that underlie microbial growth and differentiation. Knowledge of the molecular biology of microbial growth is central to mastering the biology of microbial populations and is keenly relevant to the topics of antibiotic efficacy, antibiotic resistance and persistence, and infectious disease microbiology in general.
- Some highlights: New high-resolution time-course images highlight the molecular processes of growth and cell shape determination. We expand coverage of biofilm formation and the signaling molecule cyclic-di-GMP in *Bacteria* and provide new coverage of biofilm formation in *Archaea*. The chapter also includes new coverage of endospore germination and phenotypic heterogeneity to encompass more topics within the evolving field of microbial growth from a molecular perspective.

Chapter 9

- This chapter rounds out Unit 2 by discussing the foundation for microbial diversity—how microbes undergo genetic change while still maintaining genomic integrity. This essential primer of microbial genetics also lays the groundwork for tackling the hot areas of

microbial omics and synthetic biology and provides the fundamental background necessary to comprehend the most recent concepts of microbial evolution that will unfold in later chapters.

- Some highlights: New and updated visual depictions of DNA exchange between microbes as well as updated coverage on natural competence and the role of pili in DNA uptake. Reorganized and new coverage of barriers to DNA transfer including CRISPR, the important bacterial and archaeal “immune system” whose applications are revolutionizing biology and clinical medicine.

UNIT 3: Genomics, Synthetic Biology, and Evolution

Chapter 10

- Because the genome is the blueprint for all biological traits, this chapter kicks off Unit 3 by discussing not only microbial genomics, but also methods to assay large pools of biological molecules. Various omics studies can be combined to provide a detailed picture of the vast range of capabilities possessed by a specific microbe or groups of microbes, which is essential to the topics of genetic engineering, synthetic biology, and microbial ecology.
- Some highlights: New and exciting coverage of functional genomics and high-throughput techniques to determine the role of individual genes. Reorganized and updated coverage of microbial genome content, proteomic applications, and systems biology highlight the ever-advancing field of omics.

Chapter 11

- This chapter continues the theme of Unit 3 by focusing on the unique genomes of viruses and the diverse mechanisms by which viral genomes are replicated. Knowledge of the molecular biology underlying viral replication is central not only to understanding how viruses infect their hosts and how they persist, but also for developing new clinical strategies for treating viral diseases of humans and other animals.
- Some highlights: New coverage of viral taxonomy precedes updated coverage of viruses that infect *Archaea*. Reorganized topics of bacteriophage genome replication and regulation of lysogeny in lambda directly link to foundational material in Chapter 5.

Chapter 12

- This high-energy chapter entitled “Biotechnology and Synthetic Biology” covers the essential tools of twenty-first-century biotechnology and describes how they have been applied to yield game-changing medical and other commercial products from the activities of genetically engineered microbes. Expanded coverage is provided of the rapidly advancing fields of synthetic biology and CRISPR genome editing—the latest revolutions to hit biology since discovery of the polymerase chain reaction (PCR). Text and art have been updated throughout.
- Some highlights: New coverage of how biobricks contribute to the construction of synthetic pathways and synthetic cells; the use of recombineering to revolutionize molecular cloning; genetically engineered delivery of human therapeutic agents; refactoring metabolic pathways; targeted microbial delivery of human drugs; and how gene drives could finally conquer malaria.

Chapter 13

- This chapter on microbial evolution was moved from the diversity unit into Unit 3 to emphasize its now closer ties to the unit theme of genomics. In addition to origin of life coverage, the chapter now focuses on how evolution affects the genome and ultimately the biology of the organism. The chapter ends with streamlined coverage of microbial systematics and the definition of a microbial species as a prelude to coverage of microbial diversity in Unit 4.
- Some highlights: New and expanded coverage of the evolution of both cells and viruses, including new art on cellular origins from hydrothermal systems and early bioenergetics; more extensive discussion of the mechanisms of microbial evolution from a genomic perspective, including genomic changes that occur during both vertical and horizontal gene transmission; broadened coverage of experimental evolution and genome dynamics.

UNIT 4 Microbial Diversity

Chapter 14

- Recent years have seen a flurry of fundamental new discoveries about how anaerobic organisms conserve energy. Chapter 14 has been updated to integrate information from new discoveries that lie at the heart of diverse metabolic pathways, including the discovery of electron bifurcation and energy-converting hydrogenases.
- Chapter 14 now includes a new introductory section that summarizes foundational principles of microbial physiology. This new section boils the diversity of the microbial world down into a few key principles that students can follow throughout the chapter. In addition, the chapter includes new art illustrating electron bifurcation, as well as electron flow in organisms such as sulfate reducers and methanogens. Old favorites throughout the chapter are also updated to account for recent discoveries in the field.

Chapter 15

- Chapter 15 has been reorganized and updated to emphasize relationships between metabolic and ecological diversity. New photos have been added to emphasize the morphological diversity of anoxygenic phototrophs and to demonstrate how microorganisms work together to modify their environments.

Chapter 16

- Chapter 16 has new coverage of difficult-to-cultivate bacteria, such as *Acidobacteria*, *Planctomycetes*, and *Fusobacteria*. The widespread application of metagenomic techniques have revealed that these *Bacteria* are of considerable importance in a range of habitats, including the human microbiome, but have only recently been obtained in laboratory culture.

Chapter 17

- Metagenomics has contributed greatly to our knowledge of archaeal diversity. Chapter 17 now exploits this and unveils the TACK, DPANN, and Asgard *Archaea*, some of which are the closest known relatives of the eukaryotes. We also update the diversity of mechanisms of methanogenesis in the archaeal domain.

Chapter 18

- Along with major updates on eukaryotic phylogeny, a new section is devoted to the haptophytes, including the globally and ecologically important coccolithophore *Emiliana huxleyi*. Coccolithophores play a major role in regulating global climate, illustrating the power that microbes exert over our biosphere.

UNIT 5 Microbial Ecology and Environmental Microbiology

Chapter 19

- The chapter begins a unit on ecology and environmental microbiology. The modern tools of the microbial ecologist are described with examples of how each has helped sculpt the science.
- Some highlights: A new method to visualize protein synthesis in single cells allows study of microbial activity in the environment. Metabolomics exploits new methods in mass spectrometry to unravel the complex metabolic interactions sustaining microbial communities. Nanosensor technologies are revealing how microbes alter the chemical landscape of three-dimensional surfaces. A new section explores multi-omics, which combines multiple state-of-the-art analytical tools to more fully characterize microbial communities.

Chapter 20

- The properties and microbial diversity of major microbial ecosystems including soils and aquatic systems are compared and contrasted in exciting ways.
- Some highlights: Expansive coverage of surface-attached microbial communities and how those communities are responding to plastic pollution of the environment. New understanding of the ecology of iron-oxidizing bacteria revealed by the isolation of new members of this biogeochemically significant group. The discovery in deep ocean sediments of novel *Archaea* that link this domain with *Eukarya*. Extensive coverage of marine viruses, their abundance and diversity, and how they alter the physiology of organisms they infect. Humans traveling to 10,000-meter depths in the oceans discover the most pressure-tolerant bacterium known.

Chapter 21

- Extensive coverage of the major nutrient cycles in nature and the microbes that catalyze them are presented in a fashion that allows the cycles to be taught as individual entities or as interrelated metabolic loops.
- Some highlights: Expanded coverage of the biogeochemistry of sulfur compounds highlights the importance of volatile microbial products such as dimethyl sulfide for cloud formation. Advances in the biochemistry of extracellular electron transfer add new understanding to how the ecology and diversity of microorganisms drive the biogeochemical cycling of iron and manganese. The mystery of how methane is generated (typically a strictly anoxic process) in highly oxygenated ocean surface waters is solved by discoveries in the phosphorus cycle described in a new Explore the Microbial World.

Chapter 22

- This chapter on the built environment shows how humans create new microbial habitats through construction of buildings, supporting infrastructure, and habitat modification, and which microbes take advantage of these habitats and why.
- Some highlights: The microbial metabolism of biologically produced and manufactured chlorinated organics has been expanded, as has the basis for the bioremediation of major chemical pollutants. How microbes are responding to the mountains of plastics contaminating the environment and the discovery of novel bacteria capable of degrading plastic bottles are described. New technology that improves the efficiency of wastewater treatment using granular sludge technology is presented, and the microbial response to the excessive use of common household cleansers is considered.

Chapter 23

- A chapter devoted to nonhuman microbial symbioses describes the major microbial partners that live in symbiotic associations with other microbes, with plants, and with animals other than humans.
- Some highlights: Newly revised section on symbioses between microorganisms addresses the ecological significance of phototroph switching in lichens and how certain bacterial species use electrically conductive structures to form intimate symbiotic associations. Several updates include how insect symbionts are used to combat transmission of major viral diseases of humans and how defensive chemicals produced by symbionts protect insects from predation. Detailed coverage is given to the elaborate “cross-talk” between microbe and animal needed to establish the squid light organ.

UNIT 6 Microbe–Human Interactions and the Immune System

Chapter 24

- A chapter on the human microbiome launches the unit on microbe–human interactions and the immune system by introducing and updating advances in our understanding of the microbes that inhabit the human body and their relationship to health and disease.
- Some highlights: The discovery of ultrasmall bacteria in the mouth parasitizing other bacteria brings a new twist to the microbial ecology of the oral cavity. A new section on the human virome describes how metagenomics is driving the discovery and isolation of interesting new viruses. Extensive coverage is devoted to the impact of early-life events on the development of the newborn gut microbiome and of recent successes in probiotic therapy for preventing newborn intestinal diseases.

Chapter 25

- Beginning with this chapter, the book shifts its focus to pathogenic microorganisms, the immune system, and disease. Part I of this chapter addresses microbial adherence, colonization and invasion, and pathogenicity, including important sections on virulence and virulence attenuation. Part II highlights key enzymes and toxins produced by microbes that contribute to pathogenesis.

- Some highlights: The updated text includes expanded coverage of bacterial adhesins supported by a new, two-part figure that highlights new discoveries in staphylococcal adherence. Revised coverage of virulence attenuation includes new artwork to show how this principle can be exploited for development of effective vaccines. An updated discussion of botulinum toxins reflects new findings and clearly presents both the neurotoxic mechanism and the surprising clinical utility of these extremely potent substances.

Chapter 26

- Chapter 26 opens with an overview of the immune system and the body's first-line barriers to infection. This is followed by a brief discussion of hematopoiesis before focusing on innate immune responses to pathogen invasion. The chapter provides a natural progression into adaptive immune responses covered in Chapter 27.
- Some highlights: In addition to a new chapter opener highlighting breakthroughs that link Alzheimer's disease to microbial infection, this chapter contains heavily edited text that includes a more comprehensive discussion of leukocyte diversity and an all-new description of the role of amyloid- β protein as an innate defense in the brain. Other highlights include expanded coverage of interferons and the role of natural killer cells as the primary effectors of antibody-dependent cell-mediated cytotoxicity. Finally, a fascinating new Explore the Microbial World highlights the role of pattern recognition receptors in establishing host-microbe mutualisms using hydrothermal vent tube worms as an example.

Chapter 27

- Chapter 27 begins with an essential discussion of the principles that define adaptive immunity: specificity, immune memory, lymphocyte selection, and immune tolerance. This is followed by sections that discuss the functional mechanisms of the key cells and proteins (immunoglobulins, major histocompatibility complexes, and T cell receptors) that drive adaptive immunity.
- Some highlights: The text has been heavily edited throughout, and this has produced a clearer and more informative presentation of B and T lymphocyte selection and tolerance, including a new discussion of T-dependent versus T-independent antigens. In addition, a new section dedicated to T cell activation and anergy clearly presents the important concept of the second signal required for T cell activation.

Chapter 28

- The newly reorganized Chapters 28 and 29 have emerged from materials presented in Chapter 28 of the 15th edition. Treating immune disorders and antimicrobial therapy (Chapter 28) separately from clinical diagnostic methods (Chapter 29) has produced a more teachable format, making these topics more accessible for students and easier for the instructor to plan course assignments.
- Some highlights: The text progresses smoothly from immune disorders and deficiencies to methods used to train and hone the immune response for disease prevention and treatment. New coverage of mRNA and plant-based vaccines shares the latest innovations in vaccinology. An all-new section on immunotherapy, supported by vibrant new artwork, highlights exciting advancements in the use of genetic engineering and molecular immunology to treat cancer.

UNIT 7 Infectious Diseases

Chapter 29

- To bring better focus to the material, this chapter is now solely dedicated to the clinical microbiology laboratory and includes information on lab safety, healthcare-associated infections, and a wide array of both culture-dependent and culture-independent techniques used to diagnose infectious diseases.
- Some highlights: The chapter launches with the description of an exciting new method of diagnosing tuberculosis—humanity's most notorious scourge. The text has been edited throughout for better organization and clarity, and art modifications help clarify complex diagnostic techniques. Updated terminology includes an introduction to point-of-care diagnostics.

Chapter 30

- This chapter introduces the topics and terminology of the science of epidemiology and public health. Historical and modern examples throughout emphasize key concepts such as emerging (and reemerging) diseases, epidemics and pandemics, and the public health threat associated with the development and use of weaponized microorganisms.
- Some highlights: incorporation of the most up-to-date statistics available on disease incidence and outbreaks throughout the text and in figures and tables, as well as an all-new section supported by photos on the emergence of the important healthcare-associated pathogen *Clostridioides (Clostridium) difficile*.

Chapter 31

- This is the first of four highly visual chapters that take an ecological approach to pathogenic microorganisms by considering infectious diseases based on their modes of transmission. Bacterial and viral diseases transmitted person to person by way of airborne particles, direct contact, or sexual contact are the focus here.
- Some highlights: Statistical data regarding key emerging and reemerging diseases, including measles, pertussis, influenza, hepatitis, HIV/AIDS, gonorrhea, and syphilis have been updated to reflect the most recent data available; an all-new discussion with supporting photo of the neglected tropical disease yaws helps impart knowledge and awareness of this lingering scourge.

Chapter 32

- In this chapter we examine pathogens transmitted to humans through either an animal vector or soil-contaminated wounds or objects. Many of these diseases have high morbidity and mortality rates, and in most cases, effective vaccines are not yet available.
- Some highlights: The text and figures include the most up-to-date statistics for diseases throughout the chapter, including rabies, hantavirus, spotted fever rickettsiosis, ehrlichiosis and anaplasmosis, Lyme disease, and the major tropical hemorrhagic fevers. In addition, the text now includes updated discussions of the emergence of key tickborne diseases in the United States and coverage of new strategies against dengue fever, including description of a new vaccine and the use of the bacterial endosymbiont *Wolbachia* to control the dengue virus-infected mosquito population.

Chapter 33

- Pathogens in contaminated water or food are easily transmitted to humans, with waterborne diseases being especially common in developing countries lacking adequate water treatment facilities. This chapter highlights the most prevalent water- and foodborne diseases and emphasizes the importance of clean water and proper food preparation and preservation in preventing these physically uncomfortable and occasionally fatal illnesses.
- Some highlights: Updated statistics have been incorporated for all major water- and foodborne diseases, including *Campylobacter* infections, which have now overtaken salmonellosis as the leading cause of bacterial food infection in the United States. New discussions cover recently elucidated norovirus pathology and new food safety developments, including the use of eBeam technology and bacteriophage sprays. A new overview figure of cholera infection integrates photos with artwork to emphasize key aspects of this devastating and all too common disease.

Chapter 34

- Eukaryotic pathogens present a special challenge to medicine because, on a cellular level, they are not that different from our own cells. Thus, it can be difficult to find selective targets for chemotherapeutic drugs. Yet the microbes highlighted in this highly visual chapter cause some of the most devastating and prevalent diseases today.
- Some highlights: New color photos adorn the chapter, including two stunning fluorescent micrographs of *Entamoeba histolytica*, the causative agent of amebic dysentery. Broader coverage of distinctive features of several diseases, including cyclosporiasis, toxoplasmosis, and malaria, has been seamlessly incorporated. All statistics have been updated with the most recent surveillance data to yield a global picture of fungal and parasitic diseases.

Acknowledgments

An excellent textbook is an educational resource that can only emerge from the combined contributions of a dedicated book team. In addition to the authors, the *Brock Biology of Microorganisms* (BBOM) team was composed of folks both inside and outside of Pearson. Content Manager Josh Frost paved the way for the 16th Edition of BBOM and provided the resources necessary for the authors to produce a spectacular revision in a timely fashion. Importantly, Josh also brought to BBOM his extensive experience as Content Manager of *Campbell Biology*, the leading textbook of biology worldwide. This greatly benefited BBOM, a book whose educational philosophy has traditionally paralleled that of strong majors-level biology books. The BBOM coauthor team greatly appreciated the guidance and input that Josh brought to our book.

BBOM 16e editorial and production were headed up by Michele Mangelli (Mangelli Productions), and both cover and interior designs were created by Gary Hespenheide (Hespenheide Design). Michele assembled and managed the production team and kept editorial and production on mission, on budget, and on time, and did so tirelessly in a helpful, author-friendly, and accommodating manner. The artistic magic of Gary is clearly visible in the outstanding internal design that smoothly ushers the reader through the book with highly effective organizational and navigational cues. Gary also designed the book's cover—a spectacular display of microbial diversity (photo courtesy of Professor Dr. Jörg Overmann, Braunschweig, Germany). The art team at Imagineering Art (Toronto, Canada) did an outstanding job in helping the authors link art with text and provided many helpful suggestions and options for art presentation, consistency, and style. Many thanks are extended to Michele, Gary, Jörg, and Imagineering for their outstanding efforts on BBOM 16e.

Many other people were part of the book production, editorial, or marketing team, including Karen Gulliver, Jean Lake, Kristin Piljay, Betsy Dietrich, Maureen Johnson, Susan Wang, Greg Anderson, and Elizabeth McPherson. Karen was our excellent and highly efficient production editor; she kept manuscript and pages moving smoothly through the wheels of production, graciously tolerated the authors' many requests, and accommodated our time constraints. Jean was our art coordinator, efficiently tracking and routing art and handling interactions between the art studio and the authors to ensure quality control and a timely schedule. Betsy worked with Jean and Karen to ensure an art program and text free of both bloopers and subtle errors. Kristin was our photo researcher who dug out some of the hard-to-find specialty photos that grace BBOM 16e. Susan, Greg, and Elizabeth composed an excellent accuracy review team and made numerous very helpful comments. The authors thank Karen, Jean, Kristin, Betsy, Susan, Greg, and Elizabeth for their combined contributions to the book you see in front of you today.

Special thanks go to Anita Wagner Hueftle, our spectacular copyeditor and a key part of the book team. Anita is not only a master wordsmith; her amazing gift of being able to keep track of *where* everything was said in this book and *how* everything was said in this book has helped us make the most readable, accurate, and consistent textbook of microbiol-

ogy available today. Thank you kindly, Anita; you made outstanding contributions to this edition.

We thank Alysun Estes and Krista Clark for their much-appreciated marketing support.

We are also grateful to the top-notch educators who constructed the Mastering Microbiology program that accompanies this text; these include: Candice Damiani, Jennifer Hatchel, Bryan Jennings, Ann Pater-son, Emily Booms, Ines Rauschenbach, and Monica Togna.

And last but not least, no textbook in microbiology could be published without reviewing of the manuscript and the gift of new photos from experts in the field. We are therefore extremely grateful for the assistance of the many individuals who kindly provided manuscript reviews, unpublished results, and new photos. Complete photo credits in this book are found either alongside a photo or in the photo credits listed in the back of the book. Reviewers and photo suppliers included:

- As hard as a publishing team may try, no textbook can ever be completely error-free. Although we are confident the reader will be hard pressed to find errors in *BBOM* 16e, any errors that do exist, either of commission or omission, are the responsibility of the authors. In past editions, users have been kind enough to contact us when they spot an error so we can fix it in a subsequent printing. Users should feel free to continue to contact the authors directly about any errors, concerns, questions, or suggestions they have about the book. We are always happy to hear from our readers; through the years, your comments have helped make the book stronger.

UNIT 1 The Foundations of Microbiology

1 The Microbial World 37

MICROBIOLOGYNOW Microbiology in Motion 37

- I • Exploring the Microbial World 38**
 - 1.1 Microorganisms, Tiny Titans of the Earth 38
 - 1.2 Structure and Activities of Microbial Cells 39
 - 1.3 Cell Size and Morphology 41
 - 1.4 An Introduction to Microbial Life 46
 - 1.5 Microorganisms and the Biosphere 48
 - 1.6 The Impact of Microorganisms on Human Society 49
- II • Microscopy and the Origins of Microbiology 54**
 - 1.7 Light Microscopy and the Discovery of Microorganisms 54
 - 1.8 Improving Contrast in Light Microscopy 56
 - 1.9 Imaging Cells in Three Dimensions 58
 - 1.10 Probing Cell Structure: Electron Microscopy 59
- III • Microbial Cultivation Expands the Horizon of Microbiology 61**
 - 1.11 Pasteur and Spontaneous Generation 61
 - 1.12 Koch, Infectious Diseases, and Pure Cultures 63
 - 1.13 Discovery of Microbial Diversity 65
- IV • Molecular Biology and the Unity and Diversity of Life 67**
 - 1.14 Molecular Basis of Life 67
 - 1.15 Woese and the Tree of Life 68

Explore the Microbial World
Tiny Cells 45

2 Microbial Cell Structure and Function 74

MICROBIOLOGYNOW Exploring the Microbial Cell 74

- I • The Cell Envelope 75**
 - 2.1 The Cytoplasmic Membrane 75
 - 2.2 Transporting Nutrients into the Cell 78
 - 2.3 The Cell Wall 80
 - 2.4 LPS: The Outer Membrane 83
 - 2.5 Diversity of Cell Envelope Structure 85
- II • Cell Surface Structures and Inclusions 87**
 - 2.6 Cell Surface Structures 87
 - 2.7 Cell Inclusions 89
 - 2.8 Endospores 91
- III • Cell Locomotion 94**
 - 2.9 Flagella, Archaeella, and Swimming Motility 94
 - 2.10 Surface Motility 97
 - 2.11 Chemotaxis 99
 - 2.12 Other Forms of Taxis 101
- IV • Eukaryotic Microbial Cells 102**
 - 2.13 The Nucleus and Cell Division 102
 - 2.14 Mitochondria and Chloroplasts 104
 - 2.15 Other Eukaryotic Cell Structures 106

3 Microbial Metabolism 111

MICROBIOLOGYNOW Life Begins with Metabolism 111

- I • Fundamentals of Metabolism 112**
 - 3.1 Defining the Requirements for Life 112
 - 3.2 Electron Transfer Reactions 114
 - 3.3 Calculating Changes in Free Energy 116
 - 3.4 Cellular Energy Conservation 118
 - 3.5 Catalysis and Enzymes 120
- II • Catabolism: Chemoorganotrophs 121**
 - 3.6 Glycolysis, the Citric Acid Cycle, and the Glyoxylate Cycle 122

- 12.9 Mining Genomes and Engineering Pathways 411
- 12.10 Engineering Biofuels 413

III • Synthetic Biology and Genome Editing 415

- 12.11 Synthetic Metabolic Pathways, Biosensors, and Genetic Circuits 416
- 12.12 Synthetic Cells 419
- 12.13 Genome Editing and CRISPRs 420
- 12.14 Biocontainment of Genetically Modified Organisms 424

13 Microbial Evolution and Genome Dynamics 428

MICROBIOLOGYNOW Exploring Viral Genesis 428

I • Early Earth and the Origin and Diversification of Life 429

- 13.1 Formation and Early History of Earth 429
- 13.2 Photosynthesis and the Oxidation of Earth 432
- 13.3 Living Fossils: DNA Records the History of Life 434
- 13.4 Endosymbiotic Origin of Eukaryotes 435
- 13.5 Viral Evolution 438

II • Mechanisms of Microbial Evolution 439

- 13.6 The Evolutionary Process 439
- 13.7 Experimental Evolution 441
- 13.8 Gene Families, Duplications, and Deletions 443
- 13.9 Horizontal Gene Transfer 445
- 13.10 The Evolution of Microbial Genomes 446

III • Microbial Phylogeny and Systematics 448

- 13.11 Molecular Phylogeny: Making Sense of Molecular Sequences 448
- 13.12 Microbial Systematics 452

UNIT 4 Microbial Diversity

14 Metabolic Diversity of Microorganisms 460

MICROBIOLOGYNOW Ferreting Out the Peculiar Life of Iron Bacteria 460

- I • **Introduction to Metabolic Diversity** 461
 - 14.1 Foundational Principles of Metabolic Diversity: Energy and Redox 461
 - 14.2 Autotrophic Pathways 464
- II • **Phototrophy** 466
 - 14.3 Photosynthesis and Chlorophylls 466
 - 14.4 Carotenoids and Phycobilins 470
 - 14.5 Anoxygenic Photosynthesis 471
 - 14.6 Oxygenic Photosynthesis 474
- III • **Respiratory Processes Defined by Electron Donor** 476
 - 14.7 Oxidation of Sulfur Compounds 476
 - 14.8 Iron (Fe^{2+}) Oxidation 478
 - 14.9 Nitrification 479
 - 14.10 Anaerobic Ammonia Oxidation (Anammox) 481
- IV • **Respiratory Processes Defined by Electron Acceptor** 482
 - 14.11 Nitrate Reduction and Denitrification 482
 - 14.12 Sulfate and Sulfur Reduction 484
 - 14.13 Other Electron Acceptors 486
- V • **One-Carbon (C_1) Metabolism** 488
 - 14.14 Acetogenesis 488
 - 14.15 Methanogenesis 490
 - 14.16 Methanotrophy 494
- VI • **Fermentation** 496
 - 14.17 Energetic and Redox Considerations 496
 - 14.18 Lactic and Mixed-Acid Fermentations 498
 - 14.19 Fermentations of Obligate Anaerobes 500
 - 14.20 Secondary Fermentations 502
 - 14.21 Fermentations That Lack Substrate-Level Phosphorylation 503
 - 14.22 Syntrophy 505
- VII • **Hydrocarbon Metabolism** 507
 - 14.23 Aerobic Hydrocarbon Metabolism 507
 - 14.24 Anaerobic Hydrocarbon Metabolism 508

15 Ecological Diversity of *Bacteria* 514

MICROBIOLOGYNOW Cyanobacterial Diversity and Environmental Change 514

- I • **Ecological Diversity Among Microorganisms** 515
 - 15.1 Making Sense of Microbial Diversity 515
- II • **Ecological Diversity of Phototrophic *Bacteria*** 516
 - 15.2 Overview of Phototrophic *Bacteria* 516
 - 15.3 *Cyanobacteria* 517
 - 15.4 Purple Sulfur Bacteria 521
 - 15.5 Purple Nonsulfur Bacteria and Aerobic Anoxygenic Phototrophs 523
 - 15.6 Green Sulfur Bacteria 524
 - 15.7 Green Nonsulfur Bacteria 526
 - 15.8 Other Phototrophic *Bacteria* 527
- III • **Diversity of *Bacteria* Defined by Metabolic Traits** 528
 - 15.9 Diversity of Nitrogen Fixers 528
 - 15.10 Diversity of Nitrifiers and Denitrifiers 530
 - 15.11 Dissimilative Sulfur- and Sulfate-Reducers 532
 - 15.12 Dissimilative Sulfur-Oxidizers 534
 - 15.13 Dissimilative Iron-Reducers 538
 - 15.14 Dissimilative Iron-Oxidizers 539
 - 15.15 Methanotrophs and Methylotrophs 540
- IV • **Morphologically and Ecologically Distinctive *Bacteria*** 542
 - 15.16 Microbial Predators 542
 - 15.17 Spirochetes 544
 - 15.18 Budding and Prosthecate/Stalked *Bacteria* 547
 - 15.19 Sheathed *Bacteria* 550
 - 15.20 Magnetic Microbes 551

16 Phylogenetic Diversity of *Bacteria* 555

MICROBIOLOGYNOW Bacterial Diversity and Human Health 555

ASM Recommended Curriculum Guidelines for Undergraduate Microbiology

The American Society for Microbiology (ASM) endorses a concept-based curriculum for undergraduate microbiology, emphasizing skills and concepts that have lasting importance beyond the classroom and laboratory. The ASM (in its *Curriculum Guidelines for Understanding Microbiology Education*) recommends deep understanding of 27 key concepts, 4 scientific thinking competencies, and 7 key skills. These guidelines follow scientific literacy reports and recommendations from the American Association for the Advancement of Science and the Howard Hughes Medical Institute by encouraging an active learning, student-based course. Consider these guiding statements as you progress through this book and master principles, problem solving, and laboratory skills in microbiology.

ASM Guideline Concepts and Statements

Evolution: Chapters 1, 9, 10–14, 20, 30

- Cells, organelles (e.g., mitochondria and chloroplasts), and all major metabolic pathways evolved from early prokaryotic cells.
- Mutations and horizontal gene transfer, with the immense variety of microenvironments, have selected for a huge diversity of microorganisms.
- Traditional concept of species is not readily applicable to microbes due to asexual reproduction and the frequent occurrence of horizontal gene transfer.
- Evolutionary relatedness of organisms is best reflected in phylogenetic trees.
- Human impact on the environment influences the evolution of microorganisms (e.g., emerging diseases and the selection of antibiotic resistance).

Cell Structure and Function: Chapters 1, 2, 5, 8, 11, 18

- Structure and function of microorganisms have been revealed by the use of microscopy (including bright-field, phase contrast, fluorescence, super-resolution, and electron).
- Bacteria have unique cell structures that can be targets for antibiotics, immunity, and phage infection.
- *Bacteria* and *Archaea* have specialized structures (e.g., flagella, endospores, and pili) that often confer critical capabilities.
- While microscopic eukaryotes (for example, fungi, protozoa, and algae) carry out some of the same processes as bacteria, many of the cellular properties are fundamentally different.
- Replication cycles of viruses (lytic and lysogenic) differ among viruses and are determined by their unique genomes.

Metabolic Pathways: Chapters 1, 3, 4, 7, 8, 12, 14

- *Bacteria* and *Archaea* exhibit extensive, and often unique, metabolic diversity (e.g., nitrogen fixation, methane production, anoxygenic photosynthesis).
- Interactions of microorganisms among themselves and with their environment are determined by their metabolic abilities (e.g., quorum sensing, oxygen consumption, nitrogen transformations).
- Survival and growth of any microorganism in a given environment depends on its metabolic characteristics.
- Growth of microorganisms can be controlled by physical, chemical, mechanical, or biological means.

Information Flow and Genetics: Chapters 1, 5–13

- Genetic variations can impact microbial functions (e.g., in biofilm formation, pathogenicity, and drug resistance).
- Although the central dogma is universal in all cells, the processes of replication, transcription, and translation differ in *Bacteria*, *Archaea*, and eukaryotes.
- Regulation of gene expression is influenced by external and internal molecular cues and/or signals.
- Synthesis of viral genetic material and proteins is dependent on host cells.
- Cell genomes can be manipulated to alter cell function.

Microbial Systems: Chapters 1, 15–34

- Microorganisms are ubiquitous and live in diverse and dynamic ecosystems.
- Many bacteria in nature live in biofilm communities.
- Microorganisms and their environment interact with and modify each other.
- Microorganisms, cellular and viral, can interact with both human and nonhuman hosts in beneficial, neutral, or detrimental ways.

Impact of Microorganisms: Chapters 1, 6–8, 12, 19–34

- Microbes are essential for life as we know it and the processes that support life (e.g., in biogeochemical cycles and plant and/or animal microbiota).
- Microorganisms provide essential models that give us fundamental knowledge about life processes.
- Humans utilize and harness microorganisms and their products.
- Because the true diversity of microbial life is largely unknown, its effects and potential benefits have not been fully explored.

The Microbial World

1

MICROBIOLOGYNOW

Microbiology in Motion

The microbial world is strange and fierce. It is teeming with life, ancient, diverse, and constantly changing. Microorganisms are Earth's life support system, and from our first breath they influence nearly every moment of our lives. Microbes are in our water and our food, and we carry them on us and in us. Indeed, microbes abound in any natural environment that will support life, including many environments too hostile for higher life forms.

While the microbial world is invisible, we can explore it through the science of microbiology. Microbiology evolves at a breathtaking pace. Even the microscope continues to evolve, providing an ever more detailed picture of the microbial world. The image above was made with a fluorescence microscope that uses lasers, guided by a computer, to map the three-dimensional structure of cells. The image shows neighboring human cells with their nuclei stained blue and actin filaments stained green. These cells are infected with the foodborne bacterial pathogen *Listeria monocytogenes*, stained red.

- I Exploring the Microbial World 38
- II Microscopy and the Origins of Microbiology 54
- III Microbial Cultivation Expands the Horizon of Microbiology 61
- IV Molecular Biology and the Unity and Diversity of Life 67

Listeria are soil organisms that sometimes find their way into our food. In soils they infect other microbes such as amoebae. Our cells are similar in many ways to those of microscopic organisms, and so *Listeria* finds itself well adapted to live within us. This bacterium has the unique ability to hijack cellular systems, causing actin to polymerize and propel the cell like a rocket within the host cytoplasm. The force of this propulsion causes *Listeria* to penetrate adjacent cells (image, lower left), spreading the infection. *Listeria* can also invade host vacuoles (not shown), where it hides and survives. This persistent state can prolong infection and promote resistance to antibiotic therapy. Research on *Listeria* has provided new insights on the biology of this pathogen and an ever-changing view of a microbial world in motion.

Source: Kortebe, M., et al. 2017. *Listeria monocytogenes* switches from dissemination to persistence by adopting a vacuolar lifestyle in epithelial cells. *PLoS Pathog.* 13: e1006734.

This chapter launches our journey into the microbial world. Here we will begin to discover what the science of microbiology is all about and what microorganisms are, what they do, and how they can be studied. We also place microbiology in historical context, as a process of scientific discovery driven by simple (yet powerful) experiments and insightful minds.

I • Exploring the Microbial World

The microbial world consists of microscopic organisms that have defined structures, unique evolutionary histories, and are of enormous importance to the biosphere.

1.1 Microorganisms, Tiny Titans of the Earth

Microorganisms (also called *microbes*) are life forms too small to be seen by the unaided human eye. These microscopic organisms are diverse in form and function, and they inhabit every environment on Earth that supports life. Many microbes are undifferentiated single-celled organisms, but some can form complex structures, and some are even multicellular. Microorganisms typically live in complex **microbial communities** (Figure 1.1), and their activities are regulated by interactions with each other, with their environments, and with other organisms. The science of microbiology is all about microorganisms, who they are, how they work, and what they do.

Microorganisms were teeming on the land and in the seas for billions of years before the appearance of plants and animals, and their diversity is staggering. Microorganisms represent a major fraction of Earth's biomass, and their activities are essential to sustaining life. Indeed, the very oxygen (O_2) we breathe is the result of microbial activities. Plants and animals are immersed in a world of microbes, and their evolution and survival are heavily influenced by microbial activities, by microbial symbioses, and by *pathogens*—those microbes that cause disease. Microorganisms are woven into the fabric of human life as well (Figure 1.2), from infectious diseases, to the food we eat, the water we drink, the fertility of our soils, the health of our animals, and even the fuel we put in automobiles. Microbiology is the study of the dominant form of life on Earth, and the effect that microbes have on our planet and all of the living things that call it home.

Microbiologists have many tools for studying microorganisms. Microbiology was born of the microscope, and microscopy is foundational to microbiology. Microbiologists have developed an array of methods for visualizing microorganisms, and these microscopic techniques are essential to microbiology. The cultivation of microorganisms is also foundational to microbiology. A microbial **culture** is a collection of cells that have been grown in or on a nutrient medium. A **medium** (plural, media) is a liquid or solid nutrient mixture that contains all of the nutrients required for a microorganism to grow. In microbiology, we use the word **growth** to refer to the increase in cell number as a result of cell division. A single microbial cell placed on a solid nutrient medium can grow and divide into millions or even billions of cells that form a visible **colony** (Figure 1.3). The formation of visible colonies makes it easier to see and grow microorganisms. Comprehension of the microbial basis

Figure 1.1 Microbial communities. (a) A bacterial community that developed in the depths of a small Michigan lake, including cells of various phototrophic bacteria. The bacteria were visualized using phase-contrast microscopy. (b) A bacterial community in a sewage sludge sample. The sample was stained with a series of dyes, each of which stained a specific bacterial group. From *Journal of Bacteriology* 178: 3496–3500, Fig. 2b. © 1996 American Society for Microbiology. (c) Colorized scanning electron micrograph of a microbial community scraped from a human tongue.

of disease and microbial biochemical diversity has relied on the ability to grow microorganisms in the laboratory.

The ability to grow microorganisms rapidly under controlled conditions makes them highly useful for experiments that probe the fundamental processes of life. Most discoveries relating to the molecular and biochemical basis of life have been made using microorganisms. The study of molecules and their interactions is essential to defining the workings of microbial cells, and the tools of molecular biology and biochemistry are foundational to microbiology. Molecular biology has also provided a variety of tools to study microorganisms without need for their cultivation in the laboratory. These molecular tools have greatly expanded our knowledge of microbial ecology and diversity. Finally, the tools of genomics and molecular genetics are also cornerstones of modern

Figure 1.2 Microbial applications. Microorganisms have major impacts on the world in which we live. In the chapters that follow we will learn how microorganisms impact our health, the foods we eat, the water we drink, and even the air we breathe. We will learn how microbes can be used to produce valuable products and the many ways in which microorganisms touch our lives.

microbiology and allow microbiologists to study the genetic basis of life, how genes evolve, and how they regulate the activities of cells.

In the next section, we explore the basic elements of microbial cell structure and summarize the major physiological activities that take place in all cells, regardless of their structure.

Check Your Understanding

- In what ways are microorganisms important to humans?
- Why are microbial cells useful for understanding the basis of life?
- What is a microbial colony and how is one formed?

1.2 Structure and Activities of Microbial Cells

Microbial cells are living compartments that interact with their environment and with other cells in dynamic ways. We purposely exclude viruses in most of this discussion because although they resemble cells in many ways, viruses are not cells but instead a special category of microorganism. We consider the structure, diversity, and activities of viruses in Section 1.4 and in Chapters 5 and 11.

Elements of Microbial Structure

All cells have much in common and contain many of the same components (Figure 1.4). All cells have a permeability barrier called the **cytoplasmic membrane** that separates the inside of the cell,

the **cytoplasm**, from the outside. The cytoplasm is an aqueous mixture of **macromolecules** (for example proteins, lipids, nucleic acids, and polysaccharides), small organic molecules (mostly the precursors of macromolecules), various inorganic ions, and ribosomes. All cells also contain **ribosomes**, which are the structures responsible for protein synthesis. Some cells have a **cell wall** that lends structural strength to a cell. The cell wall is a relatively permeable structure located outside the cytoplasmic membrane and is a much stronger layer than the membrane itself. Cell walls are typically found in plant cells and most microorganisms but are not found in animal cells.

There are two fundamental cell types that differ categorically in cellular organization: those having **prokaryotic** cell structure, and those having **eukaryotic** cell structure (Figure 1.4). Cells having eukaryotic cell structure are found in a group of organisms called the *Eukarya*. This group includes plants and animals as well as diverse microbial eukaryotes such as algae, protozoa, and fungi. Eukaryotic cells contain an assortment of membrane-enclosed cytoplasmic structures called **organelles** (Figure 1.4b). These include, most prominently, the DNA-containing nucleus but also mitochondria and chloroplasts, organelles that specialize in supplying the cell with energy, and various other organelles.

Prokaryotic cell structure is found within two different groups of organisms we know as *Bacteria* and *Archaea*. Prokaryotic cells have few internal structures, they lack a nucleus, and they typically lack organelles (Figure 1.4a). *Bacteria* and *Archaea* appeared long before the evolution of eukaryotes (Section 1.5). While all *Archaea* and

Figure 1.3 Microbial cells. (a) Bioluminescent (light-emitting) colonies of the bacterium *Photobacterium* grown in laboratory culture on a Petri plate. (b) A single colony can contain more than 10 million (10^7) individual cells. (c) Colorized scanning electron micrograph of cells of *Photobacterium*.

Bacteria have prokaryotic cell structure, these two groups diverged very early in the history of life and as a result many of their molecular and genetic characteristics differ at a fundamental level. Indeed, we will see later that in many ways *Archaea* and *Eukarya* are more similar to each other than either is to *Bacteria*.

Genes, Genomes, Nucleus, and Nucleoid

In addition to a cytoplasmic membrane and ribosomes, all cells also possess a DNA **genome**. The genome is the full set of genes in a cell. A gene is a segment of DNA that encodes a protein or an RNA molecule. The genome is the living blueprint of an organism; the characteristics, activities, and very survival of a cell are governed by its genome.

The genomes of prokaryotic cells and eukaryotic cells are organized into structures called **chromosomes**. In eukaryotic cells, DNA is present as several linear molecules (each one formed into its own chromosome) within the membrane-enclosed **nucleus**. By contrast, the genomes of *Bacteria* and *Archaea* are typically closed circular chromosomes (though some prokaryotic cells have linear chromosomes). The chromosome aggregates within the prokaryotic cell to form the **nucleoid**, a mass that is visible in the electron microscope (Figure 1.4a) but which is *not* enclosed by a membrane. Most prokaryotic cells have only a single chromosome, but many also contain one or more small circles of DNA distinct from that of the chromosome, called **plasmids** (Figure 1.4a). Plasmids typically contain genes that are not essential but often confer some special property on the cell (such as a unique metabolism, or antibiotic resistance). The genomes of *Bacteria* and *Archaea* are typically small and compact, and most contain between 500 and 10,000 genes encoded by 0.5 to 10 million base pairs of DNA. Eukaryotic cells typically have much larger and much less streamlined genomes than prokaryotic cells. A human cell, for example, contains approximately 3 billion base pairs, which encode about 20,000–25,000 genes.

Activities of Microbial Cells

To be competitive in nature, a microorganism must survive and reproduce. **Figure 1.5** considers structure and some of the activities that are performed by cells to drive survival and reproduction. All cells show some form of **metabolism** through which nutrients are acquired from the environment and transformed into new cellular materials and waste products. During these transformations, energy is used to support synthesis of new structures. Production of these new structures culminates in the division of the cell to form two cells. Microbial growth results from successive rounds of cell division.

Genes contain information that is used by the cell to perform the work of metabolism. Genes are decoded to form proteins that regulate cellular processes. **Enzymes**, those proteins that have catalytic activity, carry out reactions that supply energy and perform biosynthesis within the cell. Enzymes and other proteins are synthesized during *gene expression* in the sequential processes of transcription and translation. **Transcription** is the process by which the information encoded in DNA sequences is copied into an RNA molecule, and **translation** is the process whereby the information in an RNA molecule is used by a ribosome to synthesize a protein (Chapter 6). Gene expression and enzyme activity in a microbial cell are coordinated and highly regulated to ensure that the cell remains optimally tuned to its surroundings. Ultimately, microbial growth requires replication of the genome through the process of **DNA replication**, followed by cell division. All cells carry out the processes of transcription, translation, and DNA replication.

Microorganisms have the ability to sense and respond to changes in their local environment. Many microbial cells are capable of **motility**, typically by self-propulsion (Figure 1.5). Motility allows cells to relocate in response to environmental conditions. Some microbial cells undergo **differentiation**, which may result

Figure 1.4 Microbial cell structure. (a) (Left) Diagram of a prokaryotic cell. (Right) Electron micrograph of *Heliobacterium modesticaldum* (Bacteria, cell is about 1 μm in diameter) and *Thermoproteus neutrophilus* (Archaea, cell is about 0.5 μm in diameter). (b) (Left) Diagram of a eukaryotic cell. (Right) Electron micrograph of a cell of *Saccharomyces cerevisiae* (Eukarya, cell is about 8 μm in diameter). In terms of relative scale, the bacterial cell in *a* is about the same size as the mitochondria of *Saccharomyces* in *b*.

in the formation of modified cells specialized for growth, dispersal, or survival. Cells respond to chemical signals in their environment, including those produced by other cells of either the same or different species, and these signals often trigger new cellular activities. Microbial cells thus exhibit **intercellular communication**; that is, they are “aware” of their neighbors and can respond accordingly. Many prokaryotic cells can also exchange genes with neighboring cells, regardless of their species, in the process of **horizontal gene transfer**.

Evolution (Figure 1.5) results when genes in a population of cells change in sequence and frequency over time, leading to descent with modification. The evolution of microorganisms can be very rapid relative to the evolution of plants and animals. For example, the indiscriminate use of antibiotics in human and veterinary medicine has selected for the proliferation of antibiotic resistance in pathogenic bacteria. The rapid pace of microbial evolution can be attributed in part to the ability of microorganisms to grow very quickly and to acquire new genes through the process of horizontal gene transfer. Not all of the processes depicted in

Figure 1.5 occur in all cells. Metabolism, growth, and evolution, however, are universal and will be major areas of emphasis throughout this text.

We now move on to consider the diversity of cell shapes and sizes found in the microbial world.

Check Your Understanding

- What structures are universal to all type of cells?
- What processes are universal to all types of cells?
- What structures can be used to distinguish between prokaryotic cells and eukaryotic cells?

1.3 Cell Size and Morphology

Microscopic examination of microorganisms immediately reveals their **morphology**, which is defined by cell size and shape. A variety of cell shapes pervade the microbial world, and although microscopic by their very nature, microbial cells come in a variety of sizes.

Handwritten note:

- rRNA is important to check the evaluation between species

Properties of all cells:**Structure**

All cells have a cytoplasmic membrane, cytoplasm, a genome made of DNA, and ribosomes.

**Metabolism**

All cells use information encoded in DNA to make RNA and protein. All cells take up nutrients, transform them, conserve energy, and expel wastes.

1. **Catabolism** (transforming molecules to produce energy and building blocks)
2. **Anabolism** (synthesizing macromolecules)

**Growth**

Information from DNA is converted into proteins, which do work. Proteins are used to convert nutrients from the environment into new cells.

**Evolution**

Chance mutations in DNA cause new cells to have new properties, thereby promoting evolution. Phylogenetic trees built from DNA sequences capture evolutionary relationships between species.

**Properties of some cells:****Differentiation**

Some cells can form new cell structures such as a spore.

**Communication**

Cells interact with each other by chemical messengers.

**Motility**

Some cells are capable of self-propulsion.

**Horizontal gene transfer**

Cells can exchange genes by several mechanisms.

Figure 1.5 The properties of microbial cells. While cells are tremendously diverse in form and function, certain properties are shared by all cells.

Cell shape can be useful for distinguishing different microbial cells and often has ecological significance. Moreover, the very small size of most microbial cells has a profound effect on their ecology and dictates many aspects of their biology. We begin by considering cell size and then consider cell shape.

The Small World

A micrometer (μm or micron) is one-millionth of a meter in length. The unaided human eye has difficulty resolving objects that are less than $100 \mu\text{m}$ in diameter, but this is the scale of the microbial world. Most prokaryotic cells are small, ranging between 0.5 and $10 \mu\text{m}$ in length, but prokaryotic cells can vary widely in size. For example, the smallest prokaryotic cells are about $0.2 \mu\text{m}$ in diameter and the largest can be more than $600 \mu\text{m}$ long (Table 1.1). In contrast, most eukaryotic cells are larger on average than prokaryotic cells, being between 5 and $100 \mu\text{m}$ in length, but eukaryotic cells can vary widely in size too. For example, the smallest eukaryotic microorganism known is about $0.8 \mu\text{m}$ in diameter and the largest eukaryotic cells can be many centimeters in length (Section 1.4).

Cell size is influenced fundamentally by cell structure. Eukaryotic cells, owing to their complex intracellular structure and organelles (Figure 1.4), can actively transport molecules and macromolecules within the cytoplasm. Prokaryotic cells, in contrast, rely on diffusion for transport through the cytoplasm and this limits their size. While diffusion is very fast at small distances, the rate of diffusion increases as the square of the distance traveled. Hence, the metabolic rate in a prokaryotic cell varies inversely

with the square of its size. This relationship means that, as cell size increases, it becomes advantageous to have cellular structures that facilitate transport and compartmentalize cellular activities as seen in eukaryotic cells. In contrast, since diffusion is rapid at small spatial scales, high metabolic rates can be maintained in small prokaryotic cells without a need for complex cellular structures.

It is possible, though unusual, for prokaryotic cells to be visible to the human eye; the largest are more than $600 \mu\text{m}$ (0.6 mm) long. To achieve this size, these bacteria must have traits that allow them to overcome diffusional limitation. The bacterium *Epulopiscium fishelsoni* (Figure 1.6a; Figure 1.9), which is found in the gut of the surgeonfish, can be more than $75 \mu\text{m}$ wide and $600 \mu\text{m}$ long (Table 1.1). One of the traits that allows this bacterium to get so large is that it can have more than 10,000 copies of its genome distributed throughout its cytoplasm, thereby preventing diffusional limitation between the genome and any region of the cytoplasm. Cells of the largest known bacterium, the sulfur-oxidizing chemolithotroph *Thiomargarita* (Figure 1.6b, Table 1.1), are even larger than those of *Epulopiscium*, about $750 \mu\text{m}$ in diameter. *Thiomargarita* achieves this enormous size by having a large vacuole that fills the center of the cell. Hence, the cytoplasm of *Thiomargarita* occurs as a thin layer squeezed between the cytoplasmic membrane and this central vacuole. In this way, the cytoplasm is never more than $1 \mu\text{m}$ from the membrane. In addition, *Thiomargarita*, like *Epulopiscium*, also has many copies of its genome, which are distributed throughout its cytoplasm.

TABLE 1.1 Cell size and volume of some cells of *Bacteria*, from the largest to the smallest

Organism	Characteristics	Morphology	Size ^a (μm ³)	Cell volume (μm ³)	Volumes compared to <i>E. coli</i>
<i>Thiomargarita namibiensis</i>	Sulfur chemolithotroph	Cocci in chains	750	200,000,000	100,000,000×
<i>Epulopiscium fishelsoni</i> ^a	Chemoorganotroph	Rods with tapered ends	80 × 600	3,000,000	1,500,000×
<i>Beggiatoa species</i> ^a	Sulfur chemolithotroph	Filaments	50 × 160	1,000,000	500,000×
<i>Achromatium oxaliferum</i>	Sulfur chemolithotroph	Cocci	35 × 95	80,000	40,000×
<i>Lyngbya majuscula</i>	Cyanobacterium	Filaments	8 × 80	40,000	20,000×
<i>Thiovulum majus</i>	Sulfur chemolithotroph	Cocci	18	3,000	1,500×

<i>Pelagibacter ubique</i> ^a	Marine chemoorganotroph	Rods	0.2 × 0.5	0.014	0.007×
Ultra-small bacteria ^a	Uncultured, from groundwater	Variable	<0.2	0.009	0.0045×
<i>Mycoplasma pneumoniae</i>	Pathogenic bacterium	Pleomorphic ^b	0.2	0.005	0.0025×

^aWhere only one number is given, this is the diameter of spherical cells. The values given are for the largest cell size observed in each species. For example, for *T. namibiensis*, an average cell is only about 200 μm in diameter. But on occasion, giant cells of 750 μm are observed. Likewise, an average cell of *S. marinus* is about 1 μm in diameter. The species of *Beggiatoa* here is unclear, and *E. fishelsoni*, *M. bavaricum*, and *P. ubique* are not formally recognized names in taxonomy. For more on ultra-small bacteria, see Explore the Microbial World “Tiny Cells.”

^b*Mycoplasma* is a bacterium that lacks a cell wall and can thus take on many shapes (pleomorphic means “many shapes”).

Source: Data obtained from Schulz, H.N., and B.B. Jørgensen. 2001. *Annu. Rev. Microbiol.* 55: 105–137, and Luef, B., et al. 2015. *Nat. Commun.* doi:10.1038/ncomms7372.

At the opposite end of the spectrum from these large prokaryotic cells are very small prokaryotic cells. Exactly how small a cell can be is not precisely known. However, cells 0.2 μm in diameter exist (see Explore the Microbial World, “Tiny Cells”), and the lower limit is probably only a bit smaller than this. Ultimately, the lower limit to cell size is likely a function of the amount of space needed to house the essential biochemical components—proteins, nucleic acids, ribosomes and so on (Section 1.2)—that all cells need to survive and reproduce.

Surface-to-Volume Ratios, Growth Rates, and Evolution

For a cell, there are advantages to being small. Small cells have more surface area relative to cell volume and thus have a higher *surface-to-volume ratio* than larger cells. To understand this principle, consider a spherical cell. The volume of a sphere is a function of the cube of its radius ($V = \frac{4}{3}\pi r^3$), whereas its surface area is a function of the square of the radius ($S = 4\pi r^2$). Therefore, the *S/V ratio* of a coccus is $3/r$ (Figure 1.7). As cell size *increases*, its *S/V ratio decreases*.

Figure 1.6 Two very large *Bacteria*. (a) *Epulopiscium fishelsoni*. The rod-shaped cell is about 600 μm (0.6 mm) long and 75 μm wide and is shown with four cells of the protist *Paramecium* (a microbial eukaryote), each of which is about 150 μm long. (b) *Thiomargarita namibiensis*, a large sulfur chemolithotroph and currently the largest known of all prokaryotic cells. Cell widths vary from 400 to 750 μm.

✶ In bacteria, diversity is metabolic rather than morphological.

Figure 1.7 Surface area and volume relationships in cells. As a cell increases in size, its S/V ratio decreases.

To illustrate this, consider the S/V ratio for some of the cells of different sizes listed in Table 1.1: *Pelagibacter ubique*, 22; *Escherichia coli*, 4.5; and *E. fishelsoni* (Figure 1.6a), 0.05. The S/V of a rod-shaped organism can be estimated as if it were a cylinder; hence, the S/V of the cell will *decrease* as its radius *increases*.

The S/V ratio of a cell controls many of its properties, including how fast it grows (its *growth rate*) and shape. Cellular growth rate depends in part on the rate at which cells exchange nutrients and waste products with their environment. As cell size decreases, the S/V ratio of the cell increases, and this means that small cells can exchange nutrients and wastes more rapidly (per unit cell volume) than can large cells. As a result, free-living cells that are smaller tend to be more efficient than those that are larger, and any given mass

of nutrients will support the synthesis of more small cells than large cells. We will see that cell morphology is also often predicated on the effect of cell shape on S/V ratio. For example, cell shapes that increase the overall membrane area of the cell, such as those having long thin appendages or invaginations, allow bacteria to increase their S/V ratio for a given mass of cytoplasm. We will see that prokaryotic cell morphology is remarkably diverse and different cell shapes can convey different benefits upon the cell.

Major Morphologies of Prokaryotic Cells

Common morphologies of prokaryotic cells are shown in Figure 1.8. A cell that is spherical or ovoid in morphology is called a *coccus* (plural, cocci). A cylindrically shaped cell is called a *rod* or a *bacillus* (plural, bacilli). A spiral-shaped cell is called a *spirillum* (plural, spirilla). A cell that is slightly curved and comma-shaped is called a *vibrio*. A *spirochete* is a special kind of organism (► Section 15.17) that has a spiral shape but which differs from spirilla because the cells of spirochetes are flexible, whereas cells of spirilla are rigid. Some bacteria are irregular in shape. Appendages, such as stalks and hyphae, are used by some cells for attachment or to increase surface area. In addition, asymmetrical cell division such as budding can result in irregular and asymmetrical cell shapes.

Cell division has a major impact on morphology because cells that remain attached to each other can form distinctive shapes. For instance, some cocci occur in pairs (diplococci), some form long chains (streptococci), others occur in three-dimensional cubes (tetrads or sarcinae), and still others occur in grapelike clusters (staphylococci). Filamentous bacteria are long, thin, rod-shaped bacteria that divide terminally and then form long filaments composed of many cells attached end to end.

The cell morphologies described here are representative but certainly not exhaustive; many variations of these morphologies are known. For example, there can be fat rods, thin rods, short rods, and long rods, rods that occur as single cells, as pairs of cells, or rods that

Figure 1.8 Cell morphologies. Beside each drawing is a phase-contrast photomicrograph of cells showing that morphology. Coccus (cell diameter in photomicrograph, $1.5 \mu\text{m}$); rod ($1 \mu\text{m}$); spirillum ($1 \mu\text{m}$); spirochete ($0.25 \mu\text{m}$); budding ($1.2 \mu\text{m}$); filamentous ($0.8 \mu\text{m}$). All photomicrographs are of species of *Bacteria*. Not all of these morphologies are known among the *Archaea*, but cocci, rods, and spirilla are common.

Explore the Microbial World

Tiny Cells

Viruses are very small microbes and range in diameter from as small as 20 nm to almost 750 nm. Although no cells exist that are as small as most viruses, the recent discovery of ultra-small bacterial cells^{1,2} has pushed the lower limits of cell size to what microbiologists feel must be very close to the minimal value. And, because microbiologists today can deduce amazing amounts of information about cells in nature without culturing them, the lack of laboratory cultures of these tiny cells has been only a minor impediment to understanding their biology in detail.

Microbiologists collected groundwater, which travels through Earth's deep subsurface, from a Colorado (USA) aquifer (Figure 1) and passed it through a membrane filter whose

Electron cryotomography, a microscopic technique in which a specimen is examined at extremely cold temperatures without fixation (chemical treatment that can alter a cell's morphology, see Section 1.10), showed the groundwater ultramicrobacteria to consist primarily of oval-shaped cells about 0.2 μm in diameter (Figure 2). The volume of these cells was calculated to be about 1/200 that of a cell of the bacterium *Escherichia coli* (see Table 1.1) such that more than 200 of the small cells could fit into one *E. coli* cell! Each of the tiny cells contained about 50 ribosomes, which is also about 1/100 of the number present in a slowly growing (100-min generation time) cell of *E. coli*. The very small size of the groundwater ultramicrobacteria gives them an enormous surface-to-volume ratio, and it is hypothesized that this advantage benefits them in extracting resources from their nutrient-deficient habitat.

Despite the fact that the tiny groundwater bacteria have yet to be cultured in the laboratory, much is already known about them because their small genomes—less than 1 megabase (Mb) in size—were obtained and analyzed.² From a phylogenetic perspective, the different species detected were distantly related to major phyla of *Bacteria* known from environmental analyses of diverse environments but which have thus far defied laboratory culture. Further analyses showed that genes encoding the enzymes for several core metabolic pathways widely distributed among microorganisms were absent from the genomes of the groundwater ultramicrobacteria. This suggests a metabolically minimalist lifestyle for these tiny cells and a survival strategy of cross-feeding essential nutrients with neighboring species in their microbial community.

A strategy of obtaining nutrients from other organisms is one widely used in the microbial world. As we will see later in this book, many disease-causing (pathogenic or parasitic) bacteria have very small genomes that are missing many key genes otherwise necessary for a free-living lifestyle. However, the pathogenic or parasitic way of life of these

Figure 2 A tiny bacterial cell from anoxic groundwater that passed through a filter with 0.2- μm pores. The cell is not quite 0.2 μm in diameter.

microbes lets them "get away" with a minimal genomic complement because any essential molecules they are unable to biosynthesize are supplied by the host.

Although we do not yet know exactly how small a microbial cell can be, microbiologists are closing in on this number from environmental analyses such as the Colorado groundwater study. From the same samples that yielded ultra-small *Bacteria* in this study, ultra-small *Archaea* were also detected and found to contain small and highly reduced genomes.²

It is thus likely that a large diversity of very small prokaryotic cells occurs in nature, and from the continued study of these tiny cells, more precise values for both the lower limits to cell size and the minimal genomic requirements for life should emerge. Moreover, theoretical considerations of cell size have shown that DNA and proteins dominate the volume of very small cells and that the theoretical lower limit to cell size agrees closely with the smallest bacteria observed in nature thus far.³

Figure 1 Sampling the anoxic groundwater aquifer that parallels the Colorado River near Rifle, Colorado.

pores were only 0.2 μm in diameter. The liquid that passed through the filter was then subjected to microbiological analyses. Surprisingly, since filters with 0.2- μm pores have been used for decades to remove bacterial cells from solutions to generate "sterile solutions," prokaryotic cells were present in the groundwater filtrate. In fact, a diverse array of *Bacteria* were present in the filtrate, revealing that the groundwater was inhabited by a microbial community of tiny cells¹ that microbiologists have come to call ultramicrobacteria.

form into filaments. As we will see, there are even square bacteria, hexagon-shaped bacteria, and star-shaped bacteria! Cell morphologies thus form a continuum, with some shapes, such as **rods** and **cocci**, being very common, whereas others, **such as spiral, budding, and filamentous shapes, are less common.**

- Why is it that eukaryotic cells are typically larger than prokaryotic cells?
- What traits have allowed the bacteria *Epulopiscium* and *Thiomargarita* to have such large cells?

1.4 An Introduction to Microbial Life

As we have seen, microorganisms vary dramatically in size, shape, and structure. In this section we will learn more about different evolutionary (phylogenetic) lineages of cells. All cells fall into one of three major groups: *Bacteria*, *Archaea*, or *Eukarya*. These three major cell lineages are called **domains**, and all known cellular organisms belong to one of these three domains. In addition, while much of our focus in this chapter is on cellular forms of life, not all microbes form cells. In this section, we will also consider viruses, which are a group of microorganisms that lack a cellular structure. All known microorganisms can be classified into one of these four groups.

Bacteria

Bacteria have a prokaryotic cell structure (Figure 1.4a). *Bacteria* are often thought of as undifferentiated single cells with a length that ranges from 0.5 to 10 μm . While bacteria that fit this description are common, the *Bacteria* are actually tremendously diverse in appearance, size, and function (Figure 1.9). Although most bacteria are unicellular, some bacteria can differentiate to form multiple cell types and others are even multicellular (for example, *Magnetoglobus*, Figure 1.9).

Among the *Bacteria*, 30 major phylogenetic lineages (called *phyla*) have at least one species that has been grown in culture, though many more *phyla* exist which remain largely uncharacterized. Some of these *phyla* contain thousands of described species while others contain only a few. More than 90% of cultivated bacteria belong to one of only four *phyla*: *Actinobacteria*, *Firmicutes*, *Proteobacteria*, and *Bacteroidetes*. The analyses of environmental DNA sequences provide evidence for the existence of at least 80 bacterial *phyla* (Section 1.15).

Archaea

Like *Bacteria*, *Archaea* also have a prokaryotic cell structure (Figure 1.4a). The domain *Archaea* consists of five described *phyla*: *Euryarchaeota*, *Crenarchaeota*, *Thaumarchaeota*, *Nanoarchaeota*, and *Korarchaeota*. *Archaea* have historically been associated with extreme environments; the first isolates came from hot, salty, or acidic sites. But not all *Archaea* are extremophiles. *Archaea* are indeed common in

Figure 1.9 Microorganisms vary greatly in size and shape. The smallest known microbe is the circovirus (20 nm) and the **largest shown** here is the bacterium *Epulopiscium* (700 μm), which represents a 35,000-fold difference in length! Certain protozoa can be even larger than *Epulopiscium* (>2 mm long) and are visible to the unaided eye. Included in the figure are *Eukarya*: *Paramecium* (300 μm $\times$ 85 μm), diatoms (*Navicula*,

50 μm $\times$ 12 μm), yeast (*Saccharomyces*, 5 μm), and nanoflagellates (*Cafeteria*, 2 μm); *Bacteria*: *Epulopiscium* (700 μm $\times$ 80 μm), cyanobacteria (*Oscillatoria*, 10- μm -diameter multicellular filaments), *Magnetoglobus* (multicellular aggregate, 20 μm diameter), *Spirochaetes* (2–10 μm $\times$ 0.25 μm), *Flexibacter* (5–100 μm $\times$ 0.5 μm filaments), *Escherichia coli* (2 μm $\times$ 0.5 μm), *Pelagibacter*

(0.4 μm $\times$ 0.15 μm), and *Mycoplasma* (0.2 μm); *Archaea*: *Giganthauma* (10- μm -diameter multicellular filament), *Ignicoccus* (6 μm), *Nanoarchaeum* (0.4 μm), *Haloquadratum* (2 μm), *Methanosarcina* (1 μm $\times$ 0.4 μm), T4 bacteriophage (200 nm $\times$ 90 nm), *Influenza A virus* (100 nm), *Tobacco mosaic virus* (300 nm $\times$ 20 nm), *Circovirus* (20 nm).

the most extreme environments that support life, such as those associated with volcanic systems, and species of *Archaea* hold many of the records that define the chemical and physical limits of life as we know them. However, in addition to these, *Archaea* are found widely in nature in nonextreme environments. For example, methane-producing *Archaea* (methanogens) are common in wetlands and in the guts of animals (including humans) and have a major impact on the greenhouse gas composition of our atmosphere. In addition, species of *Thaumarchaeota* inhabit soils and oceans worldwide and are important contributors to the global nitrogen cycle.

Archaea are also notable in that this domain lacks any known disease-causing (pathogenic or parasitic) species of plants or animals. Most described species of *Archaea* fall within the phyla *Crenarchaeota* and *Euryarchaeota* while only a handful of species have been described for the *Nanoarchaeota*, *Korarchaeota*, and *Thaumarchaeota*. Analysis of environmental DNA sequences indicate more than 12 archaeal phyla likely exist. We discuss *Archaea* in detail in Chapter 17.

Eukarya

Plants, animals, and fungi are the most well-known groups of *Eukarya*. These groups are phylogenetically relatively young compared with *Bacteria* and *Archaea*, originating during an evolutionary burst called the *Cambrian explosion*, which began about 600 million years ago. The first eukaryotes, however, were unicellular microbes. Microbial eukaryotes, which include diverse algae and protozoa, may have first appeared as early as 2 billion years ago, well before the origin of plants, animals, and fungi (Section 1.5). The major lineages of *Eukarya* are traditionally called *kingdoms* instead of phyla. There are at least six kingdoms of *Eukarya*, and this diverse domain contains microorganisms as well as the plants and animals.

Microbial eukaryotes vary dramatically in size, shape, and physiology (Figure 1.9). Among the smallest are the nanoflagellates, which are microbial predators that can be as small as 2 μm long. In addition, *Ostreococcus*, a genus of green algae that contains species whose cells are only 0.8 μm in diameter, are smaller than many bacteria. The largest single-celled organisms are eukaryotes, but they are hardly microbial. Xenophyophores are amoeba-like, single-celled organisms that live exclusively in the deep oceans and can be up to 10 centimeters in length. In addition, plasmodial slime molds consisting of a single cytoplasmic compartment can be up to 30 cm in diameter. In Chapter 18 we consider microbial eukaryotes in detail.

Viruses

Viruses are not found on the tree of life, and for a variety of reasons, it can be argued that they are not truly alive. Although viruses can replicate—a hallmark of cells—viruses are obligate parasites that can only replicate within the cytoplasm of a host cell. Viruses are not cells, and they lack the cytoplasmic membrane, cytoplasm, and ribosomes found in all forms of cellular life. Viruses do not carry out metabolic processes; instead, they take over the metabolic systems of infected cells and turn them into vessels for producing more viruses. Unlike cells, which all have genomes composed of double-stranded DNA, viruses have genomes composed of DNA or RNA that can be either double- or single-stranded. Viral genomes are often quite small, with the smallest having only three genes. The small size of most viral genomes means that no genes are conserved among all viruses, or between all viruses and all cells.

Although they are not cells, viruses are as diverse as the cells they infect, and different viruses are known to infect cells from all three domains of life. Viruses are often classified on the basis of their structure, genome composition, and host specificity. Viruses that infect bacteria are called *bacteriophages* (or *phages*, for short). Bacteriophages have been used as model systems to explore many aspects of viral biology. While most viruses are considerably smaller than bacterial cells (Figure 1.9), there are also unusually large viruses such as the Pandora-viruses, which can be more than 1 micrometer long and have a genome that contains as many as 2500 genes, larger than that of many bacteria! We will learn much more about viruses in Chapters 5 and 11.

Check Your Understanding

- How are viruses different from *Bacteria*, *Archaea*, and *Eukarya*?
- What four bacterial phyla contain the largest number of well-characterized species?
- What phylum of *Archaea* is common worldwide in soils and in the oceans?

Figure 1.10 A summary of life on Earth through time and origin of the cellular domains. (a) At its origin, Earth was sterile and anoxic. Cellular life, in the form of *Bacteria* and *Archaea*, was present on Earth by 3.8 billion years ago (bya). The evolution of phototrophic bacteria called *Cyanobacteria* caused Earth's atmosphere to become oxygenated over time. While the first evidence for oxygen in Earth's atmosphere appears 2.4 bya, current levels of atmospheric O_2 were not achieved until 500–800 million years ago. (b) The three domains of cellular organisms are *Bacteria*, *Archaea*, and *Eukarya*. *Bacteria* and *Archaea* appeared first and *Eukarya* evolved later, diverging from the *Archaea*. LUCA, last universal common ancestor.

1.5 Microorganisms and the Biosphere

Microbes are the oldest form of life on Earth, and they have evolved to perform critical functions that sustain the biosphere. In this section we will learn how microbes have changed our planet and how they continue to do so.

A Brief History of Life on Earth

Earth is about 4.6 billion years old, and microbial cells first appeared between 3.8 and 4.3 billion years ago (Figure 1.10). During the first 2 billion years of Earth's existence, its atmosphere was anoxic (O_2 was absent), and only nitrogen (N_2), carbon dioxide (CO_2), and a few other gases were present. Only microorganisms capable of **anaerobic metabolism** (that is, metabolisms that do not require O_2) could survive under these conditions.

The evolution of **phototrophic microorganisms**—organisms that harvest energy from sunlight—occurred within 1 billion years of the formation of Earth (Figure 1.10a). The first phototrophs were anoxygenic (non-oxygen-producing), such as the purple sulfur bacteria and green sulfur bacteria we know today (Figure 1.11). *Cyanobacteria*—oxygen-producing (oxygenic) phototrophs (Figure 1.11f)—evolved nearly a billion years later (Figure 1.10a) and began the slow process of oxygenating Earth's atmosphere. These early phototrophs lived in structures called **microbial mats**, which are still found on Earth today (Figure 1.11a–c). After the oxygenation of Earth's atmosphere, multicellular life forms eventually evolved, culminating in the plants and animals we know today. But plants and animals have only existed for about half a billion years. The timeline of life on

Earth (Figure 1.10a) shows that 80% of life's history was exclusively **microbial**, and thus in many ways, Earth can be considered a **microbial planet**.

As evolutionary events unfolded, three major lineages of microbial cells—the *Bacteria*, the *Archaea*, and the *Eukarya* (Figure 1.10b)—were distinguished. All cellular organisms share certain characteristics (Figure 1.5) and as a result, certain genes are found in all cells. For example, approximately 60 genes are universally present in cells of all three domains. Examination of these genes reveals that all three domains have descended from a common ancestor, the *last universal common ancestor* (LUCA, Figure 1.10b). Over enormous periods of time, microorganisms derived from these three domains have evolved to fill every habitable environment on Earth.

Microbial Abundance and Activity in the Biosphere

Microorganisms are present everywhere on Earth that will support life. They constitute a major fraction of global biomass and are key reservoirs of nutrients essential for life. There are an estimated 2×10^{30} microbial cells on Earth. To put this number in context, the universe in all its vast extent is estimated to contain merely 7×10^{22} stars. The total amount of carbon present in all microbial cells is a significant fraction of Earth's biomass (Figure 1.12). Moreover, the total amount of nitrogen and phosphorus (essential nutrients for life) within microbial cells is almost four times that in all plant and animal cells combined. Microbes also represent a major fraction of the total DNA in the biosphere (about 31%), and their genetic diversity far exceeds that of plants and animals.

Figure 1.11 Phototrophic microorganisms. The earliest phototrophs lived in microbial mats. (a) Microbial mats in the Great Sippewissett Marsh, a salt marsh in Massachusetts, USA. (b) Mats develop a cohesive structure that forms at the sediment surface. (c) A slice through the mat shows colored layers that form

due to the presence of photopigments. Cyanobacteria form the green layer nearest the surface, purple sulfur bacteria form the purple and yellow layers below, and green sulfur bacteria form the bottommost green layer. The scale on the knife is in cm. (d) Purple sulfur bacteria, (e) green sulfur bacteria, and (f) cyanobacteria

imaged by **bright-field and phase-contrast microscopy**. Purple and green sulfur bacteria are anoxygenic phototrophs that appeared on Earth long before oxygenic phototrophs (that is, *Cyanobacteria*) evolved (see Figure 1.10a).

Figure 1.12 Contribution of microbial cells to global biomass. Microorganisms comprise a significant fraction of the carbon (C) and a majority of the nitrogen (N) and phosphorus (P) in the biomass of all organisms on Earth. C, N, and P are the macronutrients required in the greatest quantity by living organisms. Animal biomass is a minor fraction (<0.1%) of total global biomass and is not shown.

Microbes are even abundant in habitats that are much too harsh for other forms of life, such as volcanic hot springs, glaciers and ice-covered regions, high-salt environments, extremely acidic or alkaline habitats, and deep in the sea or deep in the earth at extremely high pressure. Such microorganisms are called **extremophiles** and their properties define the physiochemical limits to life as we know it (Table 1.2). We will revisit many of these organisms in later chapters and discover the special structural and biochemical properties that allow them to thrive under extreme conditions.

All ecosystems are influenced to one extent or another by microbial activities. The metabolic activities of microorganisms can change the habitats in which they live, both chemically and physically, and these changes can affect other organisms. For example, excess nutrients added to a habitat can cause aerobic (O_2 -consuming) microorganisms to grow rapidly and consume O_2 , rendering the habitat anoxic (O_2 -free). Many human activities release nutrients into the coastal oceans, thereby stimulating excessive microbial growth, which can cause enormous anoxic zones in these waters. These “dead

zones” cause massive mortality of fish and shellfish in coastal oceans worldwide, because most aquatic animals require O_2 and die if it is not available. Only by understanding microorganisms and microbiology can we predict and minimize the effects of human activity on the biosphere that sustains us.

Though diverse habitats are influenced strongly by microorganisms, their contributions are easy to overlook because of their small sizes. Within the human body, for example, more microbial cells can be present than human cells, and more than 200 microbial genes are present for every human gene. These microbes provide benefits and services that are essential to human health. In later chapters, we will return to a consideration of the ways in which microorganisms affect animals, plants, and the entire global ecosystem. This is the science of **microbial ecology**, perhaps the most exciting subdiscipline of microbiology today. We will see that microbes are important to myriad issues of global importance to humans including climate change, agricultural productivity, and even energy policy.

We focus now on the effects of microbes on humans and human activities.

Low	Acidophile	<i>Picrophilus oshimae</i>	Archaea	Acidic hot springs	−0.06	0.7 ^d	4
High	Alkaliphile	<i>Natronobacterium gregoryi</i>	Archaea	Soda lakes	8.5	10 ^e	12
Pressure							
	Barophile (piezophile)	<i>Moritella yayanosii</i>	Bacteria	Deep ocean sediments	500 atm	700 atm ^f	>1000 atm
Salt (NaCl)							
	Halophile	<i>Halobacterium salinarum</i>	Archaea	Salterns	15%	25%	32% (saturation)

^aThe organisms listed are the current “record holders” for growth in laboratory culture at the extreme condition listed.

^bAnaerobe showing growth at 122°C only under several atmospheres of pressure.

^cThe permafrost bacterium *Planococcus halocryophilus* can grow at −15°C and metabolize at −25°C. However, the organism grows optimally at 25°C and grows up to 37°C and thus is not a true psychrophile.

^d*P. oshimae* is also a thermophile, growing optimally at 60°C.

^e*N. gregoryi* is also an extreme halophile, growing optimally at 20% NaCl.

^f*M. yayanosii* is also a psychrophile, growing optimally near 4°C.

advances in understanding the important roles microorganisms play in food and agriculture, and microbiologists have exploited microbial activities to produce valuable human products, generate energy, and clean up the environment.

Microorganisms as Agents of Disease

The statistics summarized in **Figure 1.13** show how microbiologists and clinical medicine have combined to conquer infectious diseases in the past 120 years. At the beginning of the twentieth century, more than half of all humans died from infectious diseases caused by bacterial and viral **pathogens**. Today, however, infectious diseases are largely preventable due to advances in our understanding of microbiology. Microbiology has fueled advances in medicine such as vaccination and antibiotic therapy, advances in engineering such as water and wastewater treatment, advances in food safety such as pasteurization, and a better understanding of how microorganisms are transmitted. Infectious diseases now cause fewer than 5% of all deaths in countries where these interventions, made possible by microbiology, are readily available. However, while infectious diseases are preventable, the World Health Organization has documented that they still account for more than a third of all deaths in countries where microbial interventions are less available, such as those having low-income economies. As we will see later in this chapter, the development of microbiology as a science can be traced to pioneering studies of infectious disease.

While pathogens and infectious disease remain a major threat to humanity, and combating these harmful organisms remains a major focus of microbiology, most microorganisms are not harmful to humans. In fact, most microorganisms are beneficial, and in many cases are even essential to human welfare and the functioning of the planet. We turn our attention to these microorganisms and microbial activities now.

Microorganisms, Agriculture, and Human Nutrition

Agriculture benefits from nutrient cycling performed by microorganisms, in particular, the cycling of nitrogen, sulfur, and carbon compounds. For example, legumes are a diverse family of plants that include major crop species such as soybeans, peas, and lentils, among others. **Legumes** live in close association with bacteria that form structures called **nodules** on their roots. In the nodules, these bacteria convert atmospheric nitrogen (N_2) into ammonia (NH_3) through the process of **nitrogen fixation**. NH_3 is the major nutrient found in fertilizer and is used as a nitrogen source for plant growth (**Figure 1.14**). In this way bacteria allow legumes to make their own fertilizer, thereby reducing the need for farmers to apply fertilizers produced industrially. When plants die they are decomposed by bacteria in the soil, and this process produces the nutrients that form the basis of soil fertility. Bacteria regulate nutrient cycles (**Figure 1.14**), in soils and throughout the biosphere, transforming and recycling the nutrients required by plants and animals.

Also of major agricultural importance are microorganisms that inhabit the rumen of ruminant animals, such as cattle and sheep. Ruminants, like most animals, lack enzymes for breaking down the polysaccharide cellulose, the major component of plant cell walls. The digestive tract of ruminants has a large specialized chamber called the **rumen** in which cellulose is digested. The rumen contains a dense and diverse community of microorganisms that digest and ferment cellulose. Without these symbiotic microorganisms, ruminants could not digest plant matter like grass and hay, most of which consists of cellulose. Ruminants ultimately get their nutrition by metabolizing the waste products of microbial fermentation and by digesting dead microbial cells. Many domesticated and wild herbivorous mammals—including deer, bison, camels, giraffes, and goats—are also ruminants.

Figure 1.13 Death rates for the leading causes of death in the United States: 1900 and 2016. Infectious diseases were the leading causes of death in 1900, whereas today they account for relatively few deaths. Kidney diseases can be caused by microbial infections or systemic sources (diabetes, cancers, toxicities, metabolic diseases, etc.). Data are from the United States National Center for Health Statistics and the Centers for Disease Control and Prevention.

Figure 1.14 Microorganisms in modern agriculture. Root nodules on this soybean plant contain bacteria that fix atmospheric nitrogen (N_2) to form nitrogenous compounds used by the plant. Ruminant animals such as cows and sheep require rumen microbes to digest cellulose from plants. Plant matter and animal wastes are decomposed in soil to produce nutrients that are the basis of soil fertility and which are required for plant growth.

The human gastrointestinal (GI) tract lacks a rumen, but we too rely on microbial partners for our nutrition. Human enzymes lack the ability to break down complex carbohydrates (which can represent 10–30% of food energy) and so we rely on our gut microbiome for this purpose. The colon, or large intestine (Figure 1.15), follows the stomach and small intestine in the human digestive tract, and it contains about 10^{11} microbial cells per gram of colonic contents. Microbial cell numbers are low in the very acidic (pH 2) stomach (about 10^4 per gram) but increase to about 10^8 per gram near the end of the small intestine (pH 4–5) and then reach maximal numbers in the colon (pH 7) (Figure 1.15). The colon contains diverse microbial species that assist in the digestion of complex carbohydrates, and that synthesize vitamins and other nutrients essential to host nutrition. The gut microbiome develops from birth, but it can change over time with the human host. The composition of the gut microbiome has major effects on GI function and human health as we will see in Chapter 24.

Microorganisms and Food

Microbes are intimately associated with the foods we eat. Microbial growth in food can cause food spoilage and foodborne disease. The manner in which we harvest and store food (for example, canning, refrigeration, drying, salting, etc.), the ways in which we cook it, and even the spices we use, have all been fundamentally influenced by the goal of eliminating harmful organisms from our food. Microbial food safety and prevention of food spoilage is a major focus of the food industry and a major cause of economic loss every year.

While some microbes can cause foodborne disease and food spoilage, not all microorganisms in foods are harmful. Indeed,

beneficial microbes have been used for thousands of years to improve food safety and to preserve foods (Figure 1.16). For example, cheeses, yogurt, and buttermilk are all produced by microbial fermentation of dairy products. Microbial production of lactic acid in these foods improves their shelf life and prevents the growth of foodborne pathogens. Lactic acid-producing bacteria are used to produce a variety of sour-tasting foods, including sauerkraut, kimchi, pickles, and even certain sausages. Even the production of chocolate and coffee rely on microbial fermentation. Moreover, the fermentative activities of yeast are essential for baking (by generating carbon dioxide— CO_2 —to raise the dough), and for the production of alcoholic beverages (by generating alcohol). The products of microbial fermentation affect the flavor and taste of foods and can prevent spoilage as well as the growth of deleterious organisms.

Microorganisms and Industry

Microorganisms play important roles in all manner of human activity. The field of *industrial microbiology* is focused on the use of microorganisms as tools for major industries such as pharmaceuticals and brewing (Figure 1.17). For example, in large industrial settings, naturally occurring microorganisms are grown on a massive scale in bioreactors called *fermentors* to make large amounts of products, such as antibiotics, enzymes, alcohol, and certain other chemicals, at relatively low cost. By contrast, *biotechnology* employs genetically engineered microorganisms to synthesize products of high commercial value, such as insulin or other human proteins, usually on a small scale.

Microorganisms can also be used to produce *biofuels* (► Section 12.19 and Figure 12.33). For example, as previously discussed,

Figure 1.15 The human gastrointestinal tract. (a) Diagram of the human GI tract showing the major organs. (b) Scanning electron micrograph of microbial cells in the human colon (large intestine). Cell numbers in the colon can reach as high as 10^{11} per gram. As well as high numbers of cells, the microbial diversity in the colon is also quite high.

natural gas (methane, CH_4) is a product of the anaerobic metabolism of methanogenic *Archaea*. Ethyl alcohol (ethanol) is a major fuel supplement, which is produced by the microbial fermentation of glucose obtained from carbon-rich feedstocks such as sugarcane, corn, or rapidly growing grasses. Microorganisms can even convert

waste materials, such as domestic refuse, animal wastes, and cellulose, into ethanol and methane. In producing these **biofuels**, humans are simply exploiting the metabolic features of particular microbes, but at the same time, are reducing the use of fossil fuels. As we will document in Chapter 21, CO_2 levels have been rising

Figure 1.16 Fermented foods. Major fermentations in various fermented foods. It is the fermentation product (ethanol, or lactic, propionic, or acetic acids) that both preserves the food and renders it a characteristic flavor.

Wastewater Treatment: Microbes are used to clean wastewater.

Bioremediation: Microbes are used to clean contaminated environments.

Biofilms: Microbes grow on surfaces and can foul pipes and pipelines.

Biotechnology: Microbes can be genetically modified to produce high-value products such as pharmaceuticals and enzymes.

Fermentation: Microbes are used at industrial scale to make chemicals, solvents, enzymes, and pharmaceuticals.

Biofuels: Microbes are used to convert biomass into ethanol and wastes into natural gas (methane).

Figure 1.17 Industrial microbiology. Microbes have major impacts on human industry. Microbes can be used to produce valuable products and biofuels and they can also be used to clean up our wastes. Microbial biofilms have major impacts on industry because biofilms can clog and corrode pipelines and holding tanks in factories, in ships, and in the oil industry.

rapidly on Earth in the industrial era, and the link between this "greenhouse gas" and Earth's rising temperatures is firm. Thus, as a sustainable fuel source, biofuels should help cool our planet and are one facet of the "green revolution" many countries support today.

Microorganisms are also used to clean up wastes. Wastewater treatment is essential to sanitation and human health. *Wastewater treatment* relies on microbes to treat water contaminated with human waste so that it can be reused or returned safely to the environment. Waterborne diseases such as cholera and typhoid (major killers before the blossoming of microbiology; see gastroenteritis, Figure 1.13) can proliferate in the absence of proper wastewater treatment. Microbes can also be used to clean up **industrial pollution in a process called bioremediation**. In bioremediation, microorganisms are used to transform spilled oil, solvents, pesticides, heavy metals, and other environmentally toxic pollutants into nontoxic forms. Bioremediation accelerates the cleanup process either by adding special microorganisms to a polluted environment or by adding nutrients that stimulate indigenous microorganisms to degrade the pollutants. In either case the goal is to accelerate disappearance of the pollutant.

Microbes can grow in almost any environment containing liquid water, including structures made by humans. For example, **microbes often grow on submerged surfaces, forming biofilms**. Biofilms that grow in pipes and drains can cause fouling and

blockages in factory settings and pipelines, in sewers, and even in water distribution systems. In addition, biofilms that grow on ships' hulls can cause marked reductions in speed and efficiency. Biofilms can even grow in tanks that store oil and fuel, leading to spoilage of these products. We will learn that biofilms are also of great importance in medicine, as biofilms that form on implanted medical devices (► Section 4.9) can cause infections that are extremely difficult to treat.

As these examples show, the influence of microorganisms on humans is great and their activities are essential for the functioning of the planet. Or, as the famous French chemist and early microbiologist Louis Pasteur so aptly put it: "The role of the infinitely small in nature is infinitely large." Microscopes provide an essential portal through which microbiologists such as Pasteur gazed into the world of microbes. We therefore continue our introduction to the microbial world with an overview of microscopy.

II • Microscopy and the Origins of Microbiology

The microscope first revealed the microbial world, and the several different types of microscopes available today remain among the microbiologist's foremost tools.

Historically, the science of microbiology has taken its greatest leaps forward as new tools are developed and old tools improve. The microscope is the microbiologist's oldest and most fundamental tool for studying the microbial world. Indeed, microbiology did not exist before the invention of the microscope. Many forms of microscopy are available, and some are extremely powerful. Throughout this text you will see images of microorganisms that were taken through the microscope using a variety of different techniques. So let's take a moment to explore how microscopy can be used to visualize microbial cells, starting at the very beginning with the invention of the microscope.

1.7 Light Microscopy and the Discovery of Microorganisms

Although the existence of creatures too small to be seen with the naked eye had been suspected for centuries, their discovery had to await invention of the microscope. The English mathematician and natural historian Robert Hooke (1635–1703) was an excellent microscopist. In his famous book *Micrographia* (1665), the first book devoted to microscopic observations, Hooke illustrated many microscopic images including the fruiting structures of molds (**Figure 1.18**). This was the first known description of microorganisms.

The first person to see bacteria, the smallest microbial cells, was the Dutch draper and amateur microscopist Antoni van Leeuwenhoek (1632–1723). Van Leeuwenhoek constructed extremely simple microscopes containing a single lens to examine various natural substances for microorganisms (**Figure 1.19**). These microscopes were crude by today's standards, but by careful manipulation and focusing, van Leeuwenhoek was able to see bacteria. He discovered bacteria in 1676 while studying pepper-water infusions and reported his observations in a series of letters to the prestigious Royal Society of London, which published them in English translation in 1684. Drawings of some of van Leeuwenhoek's "wee animalcules," as he referred to them, are shown in **Figure 1.19b**, and a photo taken through a van Leeuwenhoek microscope is shown in **Figure 1.19c**.

Van Leeuwenhoek's microscope was a light microscope, and his design used a simple lens that could magnify an image

Figure 1.18 Robert Hooke and early microscopy. A drawing of the microscope used by Robert Hooke in 1664. The lens was fitted at the end of an adjustable bellows (G) and light focused on the specimen by a separate lens (I). Inset: Hooke's drawing of a bluish mold he found degrading a leather surface; the round structures contain spores of the mold.

Even from these simple drawings we can recognize several shapes of common bacteria: A, C, F, and G, rods; E, cocci; H, packets of cocci. (c) Photomicrograph of a human blood smear taken through a van Leeuwenhoek microscope. Red blood cells are clearly apparent.

at least 266 times. In a light microscope the sample is illuminated with visible light. **Magnification** describes the capacity of a microscope to enlarge an image. All microscopes employ lenses that provide magnification. Magnification, however, is not the limiting factor in our ability to see small objects. It is **resolution** that governs our ability to see the very small. **Resolution** is the ability to distinguish two adjacent objects as distinct and separate. The limit of resolution for a light microscope is about $0.2\ \mu\text{m}$ (μm is the abbreviation for micrometer, $10^{-6}\ \text{m}$). What this means is that two objects that are closer together than $0.2\ \mu\text{m}$ cannot be resolved as distinct and separate.

Microscopy has improved remarkably since the days of van Leeuwenhoek. Several types of light microscopy are now available, including *bright-field*, *phase-contrast*, *differential interference contrast*, *dark-field*, and *fluorescence*. With the modern compound light microscope, light is focused on the specimen by the condenser (Figure 1.20) and this light passes through the sample and is collected by the lenses. The modern compound light microscope contains two types of lenses, *objective* and *ocular*, that function in combination to magnify the image. Microscopes used in microbiology have ocular lenses that magnify $10\text{--}30\times$ and objective lenses that magnify $10\text{--}100\times$ (Figure 1.20b). The total magnification of a compound light microscope is the *product* of the magnification of its objective and ocular lenses (Figure 1.20b). Magnification of $1000\times$ is required to resolve objects $0.2\ \mu\text{m}$ in diameter, which is the limit of resolution for most light microscopes (increasing magnification beyond $1000\times$ provides little improvement in the resolution of a light microscope).

In addition to magnification, the limit of resolution for a light microscope is a function of the wavelength of light used and the light-gathering ability of the objective lens, a property known as its **numerical aperture**. There is a correlation between the magnification of a lens and its numerical aperture; lenses with higher magnification typically have higher numerical apertures. The diameter of the smallest object resolvable by any lens is equal to $0.5\lambda/\text{numerical aperture}$, where λ is the wavelength of light used. With objectives that have a very high numerical aperture (such as the $100\times$ objective), an optical-grade oil is placed between the microscope slide and the objective. Lenses on which oil is used are called *oil-immersion lenses*. Immersion oil increases the light-gathering ability of a lens, that is, it increases the amount of light that is collected and viewed by the lens.

In light microscopy, specimens are visualized because of differences in **contrast** that exist between them and their surroundings (Figure 1.21). In *bright-field microscopy*, contrast results when cells absorb or scatter light differently from their surroundings. Bacterial cells typically lack contrast, that is, their optical properties are similar to the surrounding liquid, and hence they are difficult to see well with the bright-field microscope. *Pigmented microorganisms are an exception because the color of the organism adds contrast, thus improving visualization by bright-field optics* (Figure 1.21). For cells lacking pigments there are several ways to boost contrast, and we consider these methods in the next section.

Figure 1.20 Microscopy. (a) A compound light microscope (inset photomicrograph of unstained cells taken through a phase-contrast light microscope). (b) Path of light through a compound light microscope. Figure 1.24 compares cells visualized by bright field with those visualized by phase contrast.

- Define the terms magnification and resolution.
- What is the limit of resolution for a bright-field microscope? What defines this limit?

1.8 Improving Contrast in Light Microscopy

Contrast is necessary in light microscopy to distinguish microorganisms from their surroundings. Cells can be stained to improve contrast, and staining is commonly used to visualize bacteria with

bright-field microscopy. In addition to staining, other methods of light microscopy have been developed to improve contrast with or without staining, and we consider all of these methods here.

Staining: Increasing Contrast for Bright-Field Microscopy

Dyes can be used to stain cells and increase their contrast so that they can be more easily seen in the bright-field microscope. Each class of dye has an affinity for specific cellular materials. Many dyes used in microbiology are positively charged, and for this reason, they are called *basic dyes*. Examples of basic dyes include methylene blue, crystal violet, and safranin. Basic dyes bind strongly to negatively charged cell components, such as nucleic acids and acidic polysaccharides. These dyes also stain the surfaces of cells because cell surfaces tend to be negatively charged. These properties make basic dyes useful general-purpose stains that nonspecifically stain most bacterial cells.

To perform a *simple stain*, one begins with dried preparations of cells (Figure 1.22). A clean glass slide containing a dried suspension of cells is flooded for a minute or two with a dilute solution of a basic dye, rinsed several times in water, and blotted dry. Because bacterial cells are so small, it is common to observe dried, stained preparations of those cells with a high-power (oil-immersion) lens.

Differential Stains: The Gram Stain

Stains that render different kinds of cells different colors are called *differential stains*. An important differential-staining procedure used in microbiology is the **Gram stain** (Figure 1.23). On the basis of their reaction in the Gram stain, bacteria can be divided into two major groups: **gram-positive** and **gram-negative**. After Gram staining, gram-positive bacteria appear purple-violet and gram-negative bacteria appear pink (Figure 1.23b). The color difference in the Gram stain arises because of differences in the cell wall structure of gram-positive and gram-negative cells (► Section 2.3). Staining with a basic dye such as crystal violet renders cells purple in color. Cells are then treated with ethanol, which decolorizes gram-negative cells but

1. Preparing a smear

Spread culture in thin film over slide

Dry in air

2. Heat fixing and staining

Pass slide through flame to heat fix

Flood slide with stain; rinse and dry

3. Microscopy

Place drop of oil on slide; examine with 100 $\times$ objective lens

Cell walls are different thickness of glycopeptides

Figure 1.22 Staining cells for microscopic observation. Stains improve the contrast between cells and their background. Step 3 lower right: Same cells as shown in Figure 1.20a inset but stained with a basic dye.

Procedure

1. Flood the heat-fixed smear with crystal violet for 1 min
2. Add iodine solution for 1 min
3. Decolorize with alcohol for 20 sec
4. Counterstain with safranin for 1–2 min

Result

(a)

(b)

(c)

Figure 1.23 The Gram stain. (a) Steps in the procedure. (b) Microscopic observation of gram-positive (purple) and gram-negative (pink) bacteria. The organisms are *Staphylococcus aureus* and *Escherichia coli*, respectively. (c) Cells of *Pseudomonas aeruginosa* (gram-negative, green) and *Bacillus cereus* (gram-positive, orange) stained with a one-step fluorescent staining method. This method allows for differentiating gram-positive from gram-negative bacteria in a single staining step.

not gram-positive cells. Finally, cells are counterstained with a different-colored stain, typically the red stain safranin. As a result, gram-positive and gram-negative cells can be distinguished microscopically by their different colors (Figure 1.23b).

The Gram stain is the most common staining procedure used in microbiology, and it is often performed to begin the characterization of a new bacterium. If a fluorescence microscope is available, the Gram stain can be reduced to a one-step procedure; gram-positive and gram-negative cells fluoresce different colors when treated with a special chemical (Figure 1.23c).

Phase-Contrast and Dark-Field Microscopy

Although staining is widely used in light microscopy, staining often kills cells and can distort their features. Two forms of light microscopy improve image contrast of unstained (and thus live) cells. These are phase-contrast microscopy and dark-field microscopy (Figure 1.24). The phase-contrast microscope in particular is widely used in teaching and research for the observation of living preparations.

Phase-contrast microscopy is based on the principle that cells differ in refractive index (that is, the ability of a material to alter the speed of light) from their surroundings. Light passing through a cell thus differs in phase from light passing through the surrounding liquid. This subtle difference is amplified by a device in the objective

lens of the phase-contrast microscope called the *phase ring*, resulting in a dark image on a light background (Figure 1.24b; see also inset to Figure 1.20a). The ring consists of a phase plate that amplifies the variation in phase to produce the higher-contrast image.

In the dark-field microscope, light does not pass through the specimen. Instead, light is directed from the sides of the specimen and only light that is scattered when it hits the specimen reaches the lens. Thus, the specimen appears light on a dark background (Figure 1.24c). Dark-field microscopy often has better resolution than light microscopy, and some objects can be resolved by dark-field that cannot be resolved by bright-field or even by phase-contrast microscopes. Dark-field microscopy is a particularly good way to observe microbial motility, as bundles of flagella (the structures responsible for swimming motility) are often resolvable with this technique.

Fluorescence Microscopy

The fluorescence microscope visualizes specimens that *fluoresce* (emit light). In fluorescence microscopy, cells are made to fluoresce by illuminating them from above with light of a single color. Filters are used so that only fluorescent light is seen, and thus cells appear to glow in a black background (Figure 1.25).

Cells fluoresce either because they contain naturally *fluorescent* substances such as *chlorophyll* (autofluorescence, Figure 1.25b, d)

(a)

(b)

(c)

Figure 1.24 Cells visualized by different types of light microscopy. The same field of cells of the yeast *Saccharomyces cerevisiae* visualized by (a) bright-field microscopy, (b) phase-contrast microscopy, and (c) dark-field microscopy. Cells average 8–10 μm wide.

Figure 1.25 Fluorescence microscopy. (a, b, c, d) Cyanobacteria. The same cells are observed in a and b, and likewise in c and d. The top photos are taken with phase-contrast microscopy and the bottom photos with fluorescence microscopy. The cells fluoresce because they contain chlorophyll *a* and other pigments. The image in b was generated using a filter specific for the fluorescence of chlorophyll *a*, while the image in d was generated using a permissive filter that shows fluorescence from a range of pigments that occur naturally in cyanobacteria. (e) Fluorescence photomicrograph of cells of *Escherichia coli* made fluorescent by staining with the fluorescent dye DAPI, which binds to DNA.

or because they have been stained with a fluorescent dye (Figure 1.25e). **DAPI** (4',6-diamidino-2-phenylindole) is a widely used fluorescent dye that stains cells bright blue because it complexes with the cell's DNA (Figure 1.25e). DAPI can be used to visualize cells in their natural habitats, such as soil, water, food, or a clinical specimen. Fluorescence microscopy using DAPI is widely used in clinical diagnostic microbiology and also in microbial ecology for enumerating bacteria in a natural environment or in a cell suspension (Figure 1.25e).

- What major advantage does phase-contrast microscopy have over staining?
- How can cells be made to fluoresce?

1.9 Imaging Cells in Three Dimensions

Thus far we have only considered forms of microscopy in which the rendered images are two-dimensional. Two methods of light microscopy can render a more three-dimensional image, and in this section we explore these forms of microscopy.

Differential Interference Contrast Microscopy

Differential interference contrast (DIC) microscopy is a form of light microscopy that employs a polarizer in the condenser to produce polarized light (light in a single plane). The polarized light then

passes through a prism that generates two distinct beams. These beams pass through the specimen and enter the objective lens, where they are recombined into one. Because the two beams pass through substances that differ in refractive index, the combined beams are not totally in phase but instead interfere with each other. This optical effect provides a three-dimensional perspective, which enhances subtle differences in cell structure.

Using DIC microscopy, cellular structures such as the nucleus of eukaryotic cells (Figure 1.26), or various types of inclusions present in some bacterial cells, appear more three-dimensional than in

Figure 1.26 Differential interference contrast microscopy. The yeast cells are about 8 μm wide. Note the clearly visible nucleus and compare to the bright-field image of yeast cells in Figure 1.24a.

other forms of light microscopy. DIC microscopy is typically used on unstained cells as it can reveal internal cell structures that are nearly invisible by bright-field microscopy without the need for staining (compare Figure 1.24a with Figure 1.26).

Confocal Scanning Laser Microscopy

A confocal scanning laser microscope (CSLM) is a computer-controlled microscope that couples a laser to a fluorescence microscope. The laser generates a high-contrast, three-dimensional image and allows the viewer to access several planes of focus in the specimen (Figure 1.27). The laser beam is precisely adjusted such that only a particular layer within a specimen is in perfect focus at one time. Cells struck by the laser fluoresce to generate the image as in fluorescence microscopy (Section 1.8).

Cells in CSLM preparations can also be stained with fluorescent dyes to make them more distinct (Figure 1.27a). The laser then scans up and down through the layers of the sample, generating an image for each layer. A computer assembles the images to compose the many layers into a single high-resolution, three-dimensional image. Thus, for a relatively thick specimen (such as a bacterial biofilm,

(a)

(b)

Figure 1.27 Confocal scanning laser microscopy. (a) Confocal image of a microbial biofilm community. The green, rod-shaped cells are *Pseudomonas aeruginosa* experimentally introduced into the biofilm. Cells of different colors are present at different depths in the biofilm. (b) Confocal image of a filamentous cyanobacterium growing in a soda lake. Cells are about 5 μm wide.

Figure 1.27a), not only can cells on the surface of the biofilm be observed, as with conventional light microscopy, but cells in the various layers are also observed by adjusting the plane of focus of the laser beam. CSLM is particularly useful when thick specimens need to be examined.

Check Your Understanding

- What structure in eukaryotic cells is more easily seen in DIC than in bright-field microscopy? (*Hint:* Compare Figures 1.24a and 1.26).
- Why is CSLM able to show different layers in a thick preparation while bright-field microscopy cannot?

1.10 Probing Cell Structure: Electron Microscopy

Electron microscopes use electrons instead of visible light (photons) to image cells and cell structures. In the electron microscope, electromagnets function as lenses, and the whole system operates in a vacuum (Figure 1.28). Electron microscopes are fitted with cameras to allow a photograph, called an *electron micrograph*, to be taken. Two types of electron microscopy are in routine use in microbiology: transmission and scanning.

Transmission Electron Microscopy

The *transmission electron microscope* (TEM) is used to examine cells and cell structure at very high magnification and resolution. The resolving power of a TEM is much greater than that of the light

Figure 1.28 The electron microscope. This instrument encompasses both transmission and scanning electron microscope functions.

Figure 1.29 Electron micrographs. (a) Micrograph of a thin section of a dividing bacterial cell, taken by transmission electron microscopy (TEM). The cell is about $0.8\ \mu\text{m}$ wide. (b) TEM of negatively stained molecules of hemoglobin. Each hexagonal-shaped molecule is about 25 nanometers (nm) in diameter and consists of two doughnut-shaped rings, a total of 15 nm thick. (c) Scanning electron micrograph (SEM) of bacterial cells. A single cell is about $0.75\ \mu\text{m}$ wide.

microscope, even allowing one to view structures at the molecular level (Figure 1.29). This is because the wavelength of electrons is much shorter than the wavelength of visible light, and, as we have learned, wavelength affects resolution (Section 1.7). For example, whereas the resolving power of a light microscope is about 0.2 *micrometer*, the resolving power of a TEM is about 0.2 *nanometer*, a thousandfold improvement. With such powerful resolution, objects as small as individual protein and nucleic acid molecules can be visualized by transmission electron microscopy (Figure 1.29b).

Unlike photons, electrons are very poor at penetrating; even a single cell is too thick to penetrate with an electron beam. Consequently, to view the internal structure of a cell, *thin sections* of the cell are needed, and the sections must be stabilized and stained with various chemicals to make them visible. A single bacterial cell, for instance, is cut into extremely thin (20- to 60-nm) slices, which are then examined individually by TEM (Figure 1.29a). To obtain sufficient contrast, the sections are treated with stains such as osmic acid, or permanganate, uranium, lanthanum, or lead salts. Because these substances are composed of atoms of high atomic weight, they scatter electrons well and thus improve contrast. If only the *external* features of an organism are to be observed, thin sections are unnecessary. Intact cells or cell components can be observed directly in the TEM by a technique called *negative staining* (Figure 1.29b).

Electron cryotomography (cryoET) is an imaging technique in which TEM is used to obtain three-dimensional images. In cryoET, samples are prepared by rapid freezing to very low temperatures so that they are immobilized in noncrystalline vitreous ice. They are then imaged at very low temperatures ($< -150^\circ\text{C}$), thereby preserving cell structures in their native states. Finally, samples are tilted as they are being imaged and this series of tilted images is assembled computationally to generate a three-dimensional image of the interior of the cell with a resolution of 4 nm.

Scanning Electron Microscopy

For optimal three-dimensional imaging of cells, a *scanning electron microscope* (SEM) is used. In scanning electron microscopy, the specimen is coated with a thin film of a heavy metal, typically gold. An electron beam then scans back and forth across the specimen. Electrons scattered from the metal coating are collected and projected on a monitor to produce an image (Figure 1.29c). In the SEM, even fairly large specimens can be observed, and the depth of field (the portion of the image that remains in sharp focus) is extremely good. A wide range of magnifications can be obtained with the SEM, from as low as $15\times$ up to about $100,000\times$, but only the *surface* of an object is typically visualized.

Electron micrographs taken by either TEM or SEM are black-and-white images. Although the original image contains the maximum amount of scientific information that is available, color is often added to scanning electron micrographs by manipulating them in a computer. However, such false color does not improve resolution of a micrograph. In this text, false color will be used sparingly in electron micrographs so as to present the micrographs in their original scientific context.

III • Microbial Cultivation Expands the Horizon of Microbiology

Microbes can be cultured in the laboratory, and microbial cultures have played a major role in unraveling the metabolic diversity and medical importance of the microbial world.

Following the discovery of microorganisms through microscopic methods, advances in microbial cultivation fueled major discoveries in microbiology. Important advances included the development of **aseptic technique**, a collection of practices that allow for the preparation and maintenance of **sterile** (that is, without the presence of living organisms) nutrient media and solutions (Chapter 4). Aseptic technique is essential for the isolation and maintenance of pure cultures of bacteria. **Pure cultures** are those that contain cells from only a single type of microorganism and are of great value for the study of microorganisms. Finally, **enrichment culture** techniques, which allow for the isolation from nature of microbes having particular metabolic characteristics, facilitate the discovery of diverse microorganisms.

Advances in microbial cultivation are directly responsible for success in fighting infectious disease, the discovery of microbial diversity, and the use of microbes as model systems to discover the fundamental properties of all living cells. Important advances in microbial cultivation occurred in the nineteenth century as microbiologists sought to answer two major questions of that time: (1) Does spontaneous generation occur? (2) What is the nature of infectious disease? Answers to these seminal questions emerged from the work of two giants in the field of microbiology: the French chemist Louis Pasteur and the German physician Robert Koch. We begin with the work of Pasteur.

1.11 Pasteur and Spontaneous Generation

Pasteur was a chemist by training and was one of the first to recognize that many of what were thought to be strictly chemical reactions were actually catalyzed by microorganisms. Pasteur studied the chemistry of crystal formation and he used microscopes to examine

crystal structure. His training in chemistry and microscopy prepared him to make a series of foundational discoveries to further the science of microbiology.

The Microbial Basis of Fermentation

Early in his career, Pasteur studied crystals formed during the production of alcohol. Through careful microscopic observation of tartaric acid crystals formed in wine, he observed two types of crystals that had mirror-image structures. He separated these by hand and observed that each type of crystal bent a beam of polarized light in a different direction. In this way he discovered that chemically identical substances can have optical isomers, which have different molecular structures that can influence their properties. Pasteur went on to discover that microorganisms could discriminate between optical isomers. For example, cultures of the mold *Aspergillus* (Figure 1.30) metabolized exclusively D-tartrate but not its optical isomer, L-tartrate. The fact that a living organism could discriminate between optical isomers led Pasteur to strongly suspect that many reactions previously thought to be abiotic were actually catalyzed by microbes.

While a professor of chemistry, Pasteur encountered a local businessman who produced alcohol industrially from beet juice. The businessman was losing money because many of his vats produced, instead of alcohol, a product that smelled like sour milk, which Pasteur determined to be lactic acid. In the mid-nineteenth century the production of alcohol was thought to be solely a chemical process. Pasteur studied the broth with his microscope, but instead of crystals he observed cells. Pasteur observed that the vats that produced alcohol were full of yeast, but the sour vats were full of rod-shaped bacteria. He hypothesized that these were living organisms whose growth produced either alcohol or lactic acid.

Pasteur needed to grow these organisms to prove his hypothesis. He prepared a hot-water extract of yeast cells, deducing that this would contain all of the nutrients that yeast need to grow. He then used a porcelain filter to remove all cells from this yeast extract

Figure 1.30 Louis Pasteur and his observation of isomeric discrimination by *Aspergillus*. Light micrograph of cells of the mold *Aspergillus*.

nutrient medium, rendering it sterile. If he introduced living yeast back into this sterile yeast extract medium, he could observe their growth and show the production of alcohol, but if he instead introduced the small rods, he then observed lactic acid formation. Heating of these cultures eliminated growth *and* the production of either alcohol or lactic acid. In this way he proved that fermentation is carried out by microorganisms and that different microorganisms perform different fermentation reactions.

During his work on fermentation, Pasteur observed that other organisms would often grow in his yeast extract medium. He deduced that these organisms were being introduced from the air. Pasteur's work on fermentation had prepared him to conduct a series of classic experiments on spontaneous generation, experiments that are forever linked to his name and which helped establish microbiology as a modern science.

Spontaneous Generation

The concept of **spontaneous generation** existed for thousands of years and its basic tenet can be easily grasped. If food or some other perishable material is allowed to stand for some time, it putrefies. When examined microscopically, the putrefied material is teeming with microorganisms. From where do these organisms arise? **Prior to Pasteur it was common belief that life arose spontaneously from nonliving materials, that is, by spontaneous generation.**

Mastering Microbiology

Art Activity:
Figure 1.26
Pasteur's
swan-necked
flask
experiments

Pasteur became a powerful opponent of spontaneous generation. He predicted that microorganisms in putrefying materials were descendants of cells that entered from the air or cells that had initially been present on the decaying materials. Pasteur reasoned that if food were treated in such a way as to destroy all living organisms

present—that is, if it were rendered sterile—and if it were kept sterile, it would not putrefy.

Pasteur used heat to kill contaminating microorganisms, and he found that extensive heating of a nutrient solution followed by sealing kept it from putrefying. Proponents of spontaneous generation criticized these experiments by declaring that “fresh air” was necessary for the phenomenon to occur. In 1864 Pasteur countered this objection simply and brilliantly by constructing a swan-necked flask, now called a *Pasteur flask* (Figure 1.31). In such a flask, nutrient solutions could be heated to boiling and sterilized. After the flask cooled, air could reenter, but the bend in the neck prevented particulate matter (including microorganisms) from entering the nutrient solution and initiating putrefaction. Nutrient solutions in such flasks remained sterile indefinitely. Microbial growth was observed only after particulate matter from the neck of the flask was allowed to enter the liquid in the flask (Figure 1.31c). This experiment settled the spontaneous generation controversy forever.

Pasteur's work on spontaneous generation demonstrated the importance of sterilization and led to the development of effective sterilization procedures that were eventually standardized and applied widely in microbiology, medicine, and industry. For example, the British physician Joseph Lister (1827–1912) deduced from Pasteur's discoveries that surgical infections were caused by microorganisms. He implemented a range of techniques designed to kill microorganisms and to prevent microbial infection of surgical patients. Lister is credited with the introduction of aseptic techniques for surgeries (1867), and his methods were adopted worldwide; these greatly reduced postoperative infections and greatly improved the survival rate of surgical patients. The food industry

Figure 1.31 The defeat of spontaneous generation: Pasteur's swan-necked flask experiment. In (c) the liquid putrefies because microorganisms enter with the dust. The bend in the flask allowed air to enter (a key objection to Pasteur's sealed flasks) but prevented microorganisms from entering.

also benefited from the work of Pasteur, as his principles were quickly adapted for the preservation of milk and many other foods by heat treatment, which we now call *pasteurization*.

Other Major Accomplishments of Pasteur

Pasteur went on to many other triumphs in microbiology and medicine. Some highlights include his development of vaccines for the diseases anthrax, fowl cholera, and rabies. Pasteur's work on rabies was his most famous success, culminating in July 1885 with the first administration of a rabies vaccine to a human, a young French boy named Joseph Meister who had been bitten by a rabid dog. In those days, a bite from a rabid animal was invariably fatal. News spread quickly of the success of Meister's vaccination, and of one administered shortly thereafter to a young shepherd boy, Jean-Baptiste Jupille (Figure 1.32a). Within a year several thousand people bitten by rabid animals had traveled to Paris to be treated with Pasteur's rabies vaccine.

Pasteur's fame was legendary and led the French government to establish the Pasteur Institute in Paris in 1888 (Figure 1.32b).

The shepherd boy Jean-Baptiste Jupille is shown killing a rabid dog that had attacked children. Pasteur's rabies vaccine saved Jupille's life. In France, the franc preceded the euro as a currency. (b) Part of the Pasteur Institute, Paris, France. Today this structure, built for Pasteur by the French government, houses a museum that displays some of the original swan-necked flasks used in his experiments and a chapel containing Pasteur's crypt.

Originally established as a clinical center for the treatment of rabies and other contagious diseases, the Pasteur Institute today is a major biomedical research center focused on antiserum and vaccine research and production. The medical and veterinary breakthroughs of Pasteur not only were highly significant in their own right but helped solidify the concept of the germ theory of disease, whose principles were being developed at about the same time by a second giant of this era, Robert Koch.

- How did Pasteur's experiments using swan-necked flasks defeat the theory of spontaneous generation?
- Besides ending the controversy over spontaneous generation, what other accomplishments do we credit to Pasteur?

1.12 Koch, Infectious Diseases, and Pure Cultures

Proof that some microorganisms can cause disease provided the greatest impetus for the development of microbiology as an independent biological science. As early as the sixteenth century it was suspected that some agent of disease could be transmitted from a diseased person to a healthy person. After microorganisms were discovered, a number of individuals proposed that they caused infectious diseases, but skepticism prevailed, and definitive proof was lacking. As early as 1847, the Hungarian physician Ignaz Semmelweis promoted sanitary methods including hand washing as a method for preventing infections. His methods are credited with saving many lives, but he could not prove why these methods worked and his advice was met with scorn by most of the medical community. The work of Pasteur and Lister provided strong evidence that microbes were the cause of infectious disease, but it was not until the work of the German physician Robert Koch (1843–1910) that the *germ theory* of infectious disease had direct experimental support.

The Germ Theory of Disease and Koch's Postulates

In his early work Koch studied anthrax, a disease of cattle and occasionally of humans. Anthrax is caused by the bacterium *Bacillus anthracis*. By careful microscopy and staining, Koch established that the bacteria were always present in the blood of an animal that was succumbing to the disease. However, Koch reasoned that the mere *association* of the bacterium with the disease was not actual proof of *cause and effect*, and he seized the opportunity to study cause and effect experimentally using anthrax and laboratory animals. The results of this study formed the standard by which infectious diseases have been studied ever since.

Koch used mice as experimental animals. Using appropriate controls, Koch demonstrated that when a small drop of blood from a mouse with anthrax was injected into a healthy mouse, the latter quickly developed anthrax. He took blood from this second animal, injected it into another, and again observed the characteristic disease symptoms. However, Koch carried this experiment a critically important step further. He discovered that the anthrax bacteria could be

Note that following isolation of a pure culture of the suspected pathogen, the cultured organism must both initiate the disease and be recovered from the diseased animal. Establishing the correct conditions for growing the pathogen is essential.

grown in a nutrient medium *outside the host* and that even after many transfers in laboratory culture, the bacteria still caused the disease when inoculated into a healthy animal.

On the basis of these experiments and others on the causative agent of tuberculosis, Koch formulated a set of rigorous criteria, now known as **Koch's postulates**, for definitively linking cause and effect in an infectious disease. Koch's postulates, summarized in **Figure 1.33**, stressed the importance of *laboratory culture* of the putative infectious agent followed by introduction of the suspected agent into virgin animals and recovery of the pathogen from diseased or dead animals. With these postulates as a guide, Koch, his students, and those that followed them discovered the causative agents of most of the important infectious diseases of humans and domestic animals. These discoveries also led to the development of successful treatments for the prevention and cure of many of these diseases, greatly improving the scientific basis of clinical medicine and human health and welfare (Figure 1.13).

Koch, Pure Cultures, and Microbial Taxonomy

The second of Koch's postulates states that the suspected pathogen must be isolated and grown away from other microorganisms in laboratory culture (Figure 1.33); in microbiology we say that such a culture is *pure*. To accomplish this important goal, Koch and his associates developed several simple but ingenious methods of obtaining and growing bacteria in pure culture, and many of these methods are still used today.

Koch started by using natural surfaces such as a potato slice to obtain pure cultures, but he quickly developed more reliable and reproducible growth media employing liquid nutrient solutions solidified with gelatin, and later with agar, an algal polysaccharide with excellent properties for this purpose. Along with his associate Walther Hesse, Koch observed that when a solid surface was incubated in air, masses of microbial cells called colonies developed, each having a characteristic shape and color (Figure 1.34). He inferred that each colony had arisen from a single bacterial cell that had grown to yield the mass of cells (see also Figure 1.3). Koch reasoned that each colony harbored a pure culture (a population of identical cells), and he quickly realized that solid media provided an easy way

to obtain pure cultures. Richard Petri, another associate of Koch, developed the transparent double-sided "Petri dish" in 1887, and this quickly became the standard tool for obtaining pure cultures.

Koch was keenly aware of the implications his pure culture methods had for classifying microorganisms. He observed that colonies that differed in color and size (Figure 1.34) bred true and that cells from different colonies typically differed in size and shape and often in their nutrient requirements as well. Koch realized that these differences were analogous to the criteria taxonomists had established for the classification of larger organisms, such as plant and animal species, and he suggested that the different types of bacteria should be considered as "species, varieties, forms, or other suitable designation." Such insightful thinking was important for the rapid acceptance of microbiology as a new biological science, rooted as biology was in classification during Koch's era.

Koch and Tuberculosis

Koch's crowning scientific accomplishment was his discovery of the causative agent of tuberculosis. At the time Koch began this work (1881), one-seventh of all reported human deaths were caused by tuberculosis (Figure 1.13). There was a strong suspicion that

Figure 1.34 A hand-colored photograph taken by Walther Hesse of colonies formed on agar. The colonies include those of molds and bacteria obtained during Hesse's studies of the microbial content of air in Berlin, Germany, in 1882. From Hesse, W. 1884. "Ueber quantitative Bestimmung der in der Luft enthaltenen Mikroorganismen." *Mittheilungen aus dem Kaiserlichen Gesundheitsamte*. 2: 182–207.

tuberculosis was a contagious disease, but the suspected agent had never been seen, either in diseased tissues or in culture. Following his successful studies of anthrax, Koch set out to demonstrate the cause of tuberculosis, and to this end he brought together all of the methods he had so carefully developed in his previous studies with anthrax: microscopy, staining, pure culture isolation, and an animal model system (Figure 1.33).

The bacterium that causes tuberculosis, *Mycobacterium tuberculosis*, is very difficult to stain because *M. tuberculosis* cells contain large amounts of a waxlike lipid in their cell walls. Nevertheless, Koch devised a staining procedure for *M. tuberculosis* cells in lung tissue samples. Using this method, he observed the blue, rod-shaped cells of *M. tuberculosis* in tubercular tissues but not in healthy tissues (Figure 1.35). Obtaining cultures of *M. tuberculosis* was not easy, but eventually Koch succeeded in growing colonies of this organism on a solidified medium containing blood serum. Under the best of conditions, *M. tuberculosis* grows slowly in culture, but Koch's persistence and patience eventually led to pure cultures of this organism from human and animal sources.

From this point Koch used his postulates (Figure 1.33) to obtain definitive proof that the organism he had isolated was the cause of the disease tuberculosis. Guinea pigs can be readily infected with *M. tuberculosis* and eventually succumb to systemic tuberculosis. Koch showed that tuberculous guinea pigs contained masses of *M. tuberculosis* cells in their lungs and that pure cultures obtained from such animals transmitted the disease to healthy animals. In this way, Koch successfully satisfied all four of his postulates, and the cause of tuberculosis was understood. Koch announced his discovery of the cause of tuberculosis in 1882, and for this accomplishment

he was awarded the 1905 Nobel Prize for Physiology or Medicine. Koch had many other triumphs in the growing field of infectious diseases, including the discovery of the causative agent of cholera (the bacterium *Vibrio cholerae*) and the development of methods to diagnose infection with *M. tuberculosis* (the tuberculin skin test).

- How do Koch's postulates ensure that cause and effect of a given disease are clearly differentiated?
- What advantages do solid media offer for the isolation of microorganisms?
- What is a pure culture?

1.13 Discovery of Microbial Diversity

As microbiology entered the twentieth century, its initial focus on basic principles, methods, and medical aspects broadened to include studies of the microbial diversity of soil and water and the metabolic processes that microorganisms carried out in these habitats. Major contributors of this era included the Dutchman Martinus Beijerinck and the Russian Sergei Winogradsky.

Sergei Winogradsky and Chemolithotrophy

Sergei Winogradsky (1856–1953) was interested in the bacterial diversity of soils and waters and was highly successful in isolating several notable bacteria from natural samples. Winogradsky was particularly interested in bacteria that cycle nitrogen and sulfur compounds, such as the nitrifying bacteria and the sulfur bacteria (Chapters 14 and 15). He studied *Beggiatoa*, which are large sulfur-oxidizing bacteria found in marine sediments. *Beggiatoa* are morphologically distinctive and readily identified under the microscope (Figure 1.36), but Winogradsky found that they would not grow on the rich nutrient media used by Koch and Pasteur. In order to grow these *Beggiatoa*, Winogradsky designed a medium that chemically imitated the environment in which *Beggiatoa* lived. He showed that *Beggiatoa* are able to grow in the absence of organic nutrients, and that their growth requires only inorganic substances (compounds lacking carbon–carbon bonds). In this way, Winogradsky was the first to define **chemolithotrophy**, which is any metabolic process in which energy for growth is produced using only *inorganic* chemical compounds. Winogradsky also revealed that these chemolithotrophic bacteria obtain their carbon from CO₂, much like plants, though they get their energy from chemical reactions rather than from light. Winogradsky further showed that these organisms, which he called *lithotrophs* (meaning, literally, “stone eaters”), are widespread in nature.

Martinus Beijerinck, the Enrichment Culture Technique, and Nitrogen Fixation

Martinus Beijerinck (1851–1931) was a professor at the Delft Polytechnic School in Holland and a contemporary of Winogradsky. Beijerinck's greatest contribution to the field of microbiology was his clear formulation of the *enrichment culture technique*. Enrichment cultures were used by both Beijerinck and Winogradsky to discover many unique forms of metabolism that we now know to be essential to nutrient cycling in nature.

(b) *Beggiatoa*, a sulfur chemolithotroph (compare with ► Figure 15.32a).

The growth media used by Pasteur and Koch (for example, yeast extract media) were rich in a wide variety of nutrients. These media support the growth of many microorganisms and are often suitable for growing pathogenic bacteria, but as Winogradsky discovered, most bacteria found in nature do not grow well on such media. Enrichment culture techniques are used to selectively encourage the growth of specific microorganisms. To do this, enrichment cultures employ culture media and selective incubation conditions that are deliberately designed to favor only certain types of microbes.

For example, Winogradsky used enrichment culture to isolate the first nitrogen-fixing bacterium. He devised a liquid growth medium that lacked a source of nitrogen, inoculated this medium with soil, and incubated it in the presence of air. He knew that all living things require nitrogen, and so when he observed bacteria growing in the medium he knew that they must be getting their nitrogen from N_2 in the air. In this way he enriched for and ultimately isolated the anaerobic nitrogen-fixing bacterium *Clostridium pasteurianum*, becoming the first to demonstrate the process of nitrogen fixation. The growth of nitrogen-fixing bacteria was favored in the enrichment culture because only those bacteria that can use nitrogen from

Lesley Robertson and the Kluwer Laboratory Museum, Delft University of Technology

Figure 1.37 Martinus Beijerinck and *Azotobacter*. The first aerobic nitrogen-fixing bacterium, *Azotobacter chroococcum*, was isolated by M. Beijerinck in 1900. The image is a painting by M. Beijerinck's sister, Henriëtte Beijerinck, showing cells of *Azotobacter chroococcum*. Beijerinck used such paintings to illustrate his lectures. Compare these drawings of *A. chroococcum* cells with the photomicrograph of cells of *Azotobacter* in Figure 15.24.

the air can grow on media that lack a nitrogen source such as ammonia or nitrate. Beijerinck used a similar technique shortly thereafter to isolate the first aerobic nitrogen-fixing bacterium, *Azotobacter* (Figure 1.37). Beijerinck also devised a medium to isolate rhizobia and proved that these bacteria cause root nodules to form on legumes and that they perform nitrogen fixation within the nodules (Figure 1.14).

Using the enrichment culture technique, Beijerinck and Winogradsky isolated the first pure cultures of many important soil and aquatic microorganisms. For example, Winogradsky isolated the first nitrifying bacteria using an enrichment medium that contained ammonium salts and CO_2 since these chemolithotrophic bacteria oxidize ammonium as an energy source and are autotrophic. Beijerinck was the first to isolate sulfur-cycling bacteria such as sulfate-reducing bacteria and sulfur-oxidizing bacteria, fermentative bacteria such as the lactic acid bacteria, and many other physiological types of bacteria as well as microbial eukaryotes such as green algae.

Beijerinck was also the first person to observe a virus. While studying “mosaic disease” of tobacco, Beijerinck used selective filters to show that the infectious agent in this disease was smaller than any bacterium and that it somehow became incorporated into cells of the living host plant. In this insightful work, Beijerinck described not only the first virus, but also the basic principles of virology, which we expand upon in Chapters 5 and 11.

IV • Molecular Biology and the Unity and Diversity of Life

Molecular analyses of microbial cells have unveiled the biochemical principles that govern all life and the evolutionary position of microbes in the tree of life.

The development of aseptic technique and methods for the enrichment, isolation, and propagation of bacteria at the end of the nineteenth century gave rise to explosive growth in the pace of microbiological discovery. Moreover, microbiologists realized that the ability to grow bacteria rapidly and in controlled laboratory conditions made them excellent model systems for exploring the fundamental nature of life.

1.14 Molecular Basis of Life

Experiments with bacterial cultures in the twentieth century were critical in forming the foundations of molecular biology, molecular genetics, and biochemistry. Microbiologists came to realize that while microorganisms were incredibly diverse, all cells appeared to operate on similar basic principles. Thus, the search was on for the overarching molecular processes that define life itself.

Unity in Biochemistry

Albert Jan Kluyver (1888–1956) was Beijerinck's successor at what was then called the Delft Institute of Technology. Kluyver recognized that though microbial diversity was tremendous, all microorganisms used many of the same biochemical pathways and their metabolic processes were governed by similar thermodynamic constraints.

Kluyver promoted the study of comparative biochemistry to identify the unifying features of all cells. He famously proclaimed, "From elephant to butyric acid bacterium—it is all the same!" This was later reformulated by Jacques Monod (1910–1976) into the expression, "What is true for *E. coli* is also true for the elephant," a statement that proclaimed the importance of working with bacteria to understand the fundamental principles that govern all living things.

The use of microbes as metabolic model systems led to the discovery that certain macromolecules and biochemical reactions are universal, and that to understand their function in one cell is to understand their function in all cells. We will learn about these fundamental macromolecules and biochemical processes in later chapters. These discoveries were of central importance to understanding microbial evolution, and none were more important than the discovery of DNA as the molecular basis of heredity, a discovery that is less than 80 years old.

Cracking the Code of Life

In the early twentieth century, it was clear that some molecule carried the hereditary information from parent to offspring, but the molecular basis of heredity remained a mystery. Most biologists thought that proteins carried this hereditary information. DNA had been discovered but it was thought to be merely a structural molecule, and too simple in its composition to encode cellular functions. The hunt for the molecular basis of heredity began in earnest with a key experiment by the British bacteriologist Frederick Griffith (1879–1941).

Griffith worked with a virulent strain of *Streptococcus pneumoniae*, a cause of bacterial pneumonia in both humans and mice. This strain, strain S, produced a polysaccharide coat (that is, a capsule, ► Section 2.6) that caused cells to form smooth colonies on agar media and conferred the ability to kill infected mice (Figure 1.38a).

Figure 1.38 Early evidence that DNA is the molecular basis of heredity. (a) Griffith's experiment showed that bacteria can transfer genetic information. *Streptococcus pneumoniae* strain R makes rough colonies on agar media and does not kill mice, but strain S makes smooth colonies and does kill mice. Heat-killed cells of strain S do not cause disease, but if these killed cells are mixed with cells of strain R, then strain R is "transformed" to the S type and begins to make smooth colonies and kill mice. (b) The Avery–MacLeod–McCarty experiment showed that DNA contains genetic information. DNA isolated from strain S can transform strain R to cause disease, though the DNA itself does not cause disease. Degraded DNA (the control in the experiment) lacks the ability to transform strain R.

A related strain, strain R, lacked this polysaccharide and produced “rough” colonies that did not cause disease. However, Griffith observed that strain R could be *transformed* to type S, forming smooth colonies and causing disease, when it was mixed with the dead remains of cells of strain S (Figure 1.38a). He reasoned that some molecule that contained genetic information must have been transferred from strain R to strain S in this process, and this experiment showed that genetic transfer could be studied in bacteria.

Later, the Avery–MacLeod–McCarty experiment (1944), named for three scientists at the Rockefeller University, would show that this “transforming principle” was DNA. They treated the dead remains of cells of strain S with chemicals and enzymes that destroyed protein and left behind only DNA. They then repeated Griffith’s experiment with the pure DNA of strain S and showed that this DNA was sufficient to cause transformation, causing strain R cells to become S-type cells and virulent (Figure 1.38b). They also demonstrated that transformation failed if the DNA from strain S was degraded. Collectively, these experiments proved that DNA is the genetic material of cells.

The discovery that DNA is the basis of heredity was followed by intense efforts to understand how this molecule stores genetic information. The structure of DNA was ultimately solved by James D. Watson (1928–) and Francis Crick (1916–2004) using X-ray diffraction images of DNA taken by their colleague Rosalind Franklin (1920–1958). They revealed that DNA is composed of a double helix that contains four nitrogenous bases: guanine, cytosine, adenine, and thymine, which form the genetic code (► Section 6.1). Later research would reveal how the genetic code is read from DNA and translated into protein, and these principles are covered in Chapter 6. Once again, however, this research to crack the code of life was enabled by a microbial model system, in this case, the bacterium *Escherichia coli*.

From DNA to Evolutionary Insight

Not long after the discovery that genetic information is encoded in the sequence of biological molecules, Emile Zuckerkandl (1922–2013) and Linus Pauling (1901–1994) proposed that molecular sequences could be used to reconstruct evolutionary relationships. They recognized that evolution, as described by Darwin, required variation in offspring and that these variations must be caused by changes in molecular sequences. They predicted that these sequence differences occur randomly in a clocklike fashion over time. This led to the conclusion that the evolutionary history of organisms is inscribed in the sequence of molecules such as DNA. Carl Woese seized upon these insights to pursue the ambitious goal of reconstructing the evolutionary history of all cells, and we explore the events that led up to this seminal discovery in evolutionary biology now.

Check Your Understanding

- Describe the experiments that proved DNA was the transforming principle described by Griffith.
- Why are microbes useful as model organisms to understand basic principles of biology?

1.15 Woese and the Tree of Life

Evolutionary relationships between microorganisms remained a mystery until it was discovered that certain molecular sequences maintain a record of evolutionary history. Here we will examine how the sequence of **ribosomal RNA (rRNA)** genes, present in all cells, revolutionized the understanding of microbial evolution and made it possible to construct the first universal tree of life. Ribosomal RNAs are components of the *ribosome*, the biosynthetic machine that all cells use to make proteins (Section 1.2).

Figure 1.39 Early efforts to depict the universal tree of life. A conceptual tree of life proposed by Ernst Haeckel in *Generelle Morphologie der Organismen* (1866) shortly after Darwin published *On the Origin of Species* (1859). Haeckel proposed that four main groups of organisms (Plantae, Animalia, Protista, and Moneres) evolved from a common single-celled ancestor. The group that Haeckel proposed as Moneres included all microbes having prokaryotic cell structure, which we know today as *Bacteria* and *Archaea*.

Early Attempts to Portray the Evolutionary History of Life

For over a hundred years, following the 1859 publication of Charles Darwin's *On the Origin of Species*, evolutionary history was studied primarily with the tools of paleontology (through examining fossils) and comparative biology (through comparing the traits of living organisms). These approaches led to progress in understanding the evolution of plants and animals, but they were powerless to explain the evolution of microorganisms. The vast majority of microorganisms do not leave behind fossils, and their morphological and physiological traits provide few clues about their evolutionary history. Moreover, microorganisms do not share any morphological traits with plants and animals. Thus, it was impossible to create a robust evolutionary framework that included microorganisms.

The first attempt to depict the common evolutionary history of all living cells was published by Ernst Haeckel in 1866 (Figure 1.39). Haeckel correctly suggested that single-cell organisms, which he called *Monera* (labeled as Moneres near the root of the tree shown in Figure 1.39), were ancestral to other forms of life, but his scheme, which included plants, animals, and protists, did not attempt to resolve evolutionary relationships among microorganisms. The situation was little changed as late as 1969 when Robert Whittaker proposed a five-kingdom classification scheme (Figure 1.40). Whittaker's scheme distinguished the fungi as a distinct lineage, but it was still largely impossible to resolve evolutionary relationships among most microorganisms. Hence, our understanding of microbial evolution had made little progress since Haeckel's day.

Molecular Sequence Data Revolutionized Microbial Phylogeny

Everything changed after the structure of DNA was discovered and it was recognized that evolutionary history is recorded in DNA sequences. Carl Woese (1928–2012), a professor at the University of Illinois (USA), realized in the 1970s that the sequence of ribosomal RNA (rRNA) molecules and the genes that encode them could be used to infer evolutionary relationships between organisms. Woese recognized that genes encoding rRNAs were excellent candidates for phylogenetic analysis because they were (1) present in all cells, (2) functionally constant, (3) highly conserved (slowly changing) in their nucleic acid sequences, and (4) of adequate length to provide a deep view of evolutionary relationships.

Woese compared the sequences of rRNA molecules from many microorganisms. Among the first microbes he examined were methanogens. To his astonishment, he found that the rRNA sequences from methanogens were distinct from those of both *Bacteria* and *Eukarya*, the only two domains recognized at that time. He named this new group of prokaryotic cells the *Archaea* (originally *Archaeobacteria*) and recognized them as the third domain of life alongside the *Bacteria* and the *Eukarya* (Figure 1.41b). More importantly, Woese demonstrated that the analysis of rRNA gene sequences could be used to reveal evolutionary relationships between *all cells*, providing the first effective tool for the evolutionary classification of microorganisms.

The Tree of Life Based on rRNA Gene Sequences

The universal tree of life based on rRNA gene sequences (Figure 1.41b) is a genealogy of all life on Earth. It is a true **phylogenetic tree**, a diagram that depicts the evolutionary history—the **phylogeny**—of all cells

Figure 1.40 Later efforts to depict the universal tree of life. A conceptual tree of life published by Robert H. Whittaker (1969). Whittaker recognized the same groups as Haeckel (Figure 1.39), but he was the first to propose adding Fungi as a distinct kingdom. Compare this tree to Haeckel's tree and consider how little our knowledge of microbial evolution had changed between 1866 and 1969, prior to the development of nucleic acid sequencing.

and clearly reveals the three domains. The root of the universal tree represents a point in time when all extant life on Earth shared a common ancestor, the last universal common ancestor, LUCA (Figures 1.10b and 1.41b). From the last universal common ancestor of all cells, evolution proceeded along two paths to form the domains *Bacteria* and *Archaea*. At some later time, the domain *Archaea* diverged to distinguish the *Eukarya* from the *Archaea* (Figures 1.10b and 1.41b). The three domains of cellular life are evolutionarily distinct and yet they share features indicative of their common descent from a universal cellular ancestor.

Revealing the Extent of Microbial Diversity

The tools Woese developed to build the tree of life were first used to determine the evolutionary history of microorganisms grown in pure culture (Figure 1.41a). However, Norman Pace (1942–), a professor at the University of Colorado (USA), realized that Woese's approach could be applied to rRNA molecules isolated *directly from the environment* as a way to probe the diversity of natural microbial communities without first cultivating their component organisms (Chapter 19). These **cultivation-independent** methods of rRNA gene analysis pioneered by Pace greatly improved our picture of microbial diversity (Figure 1.42). Despite many advances in the culturing of microorganisms from nature, many microbes have not yet been brought into laboratory culture. Hence, **cultivation-independent** methods provide us with valuable insights into the diversity and activities of microbes found in nature and oftentimes provide crucial hints for how they can be cultured. We also now know that although much progress has been made in describing microbial diversity, much of this diversity is yet to be explored and thus our work to describe the microbial world has only just begun.

Figure 1.41 Evolutionary relationships and the phylogenetic tree of life. (a) The technology behind ribosomal RNA gene phylogenies. (1) DNA is extracted from cells. (2) Copies of the gene encoding rRNA are made by the polymerase chain reaction (PCR, a technique for making multiple copies of nucleic acid sequences, ► Section 12.1). (3) The gene is sequenced, and (4) the sequence is aligned and analyzed with sequences of the same gene from other

organisms. A computer algorithm makes pairwise comparisons at each base and (5) generates a phylogenetic tree that depicts evolutionary relationships. In the example shown, the sequence differences are highlighted in yellow and are as follows: organism 1 versus organism 2, three differences; 1 versus 3, two differences; 2 versus 3, four differences. Thus organisms 1 and 3 are closer relatives than are 2 and 3 or 1 and 2. (b) The phylogenetic tree of life based on

the analysis of rRNA gene sequences as proposed by Carl Woese (adapted from Woese, C.R., et al. *PNAS* 87: doi.org/10.1073/pnas.87.12.4576). The tree shows the three domains of organisms and a few representative groups in each domain. See detailed discussion of using molecular sequences as phylogenetic tools in Section 13.11.

Improvements in DNA sequencing technology have greatly improved our ability to study *Bacteria* and *Archaea* (Figure 1.42b). While the analysis of rRNA genes remains a cornerstone of microbial ecology, we now have the ability to sequence *entire microbial genomes* instead of just individual genes. Jo Handelsman (1959–), a professor at the University of Wisconsin (USA), was the first to propose *metagenomics*, a technique in which fragments of microbial genomes (or even entire genomes) can be recovered from a sample of environmental DNA. Metagenomics, the study of genomic information recovered directly from the environment, is currently providing us with profound insights on the evolution and diversity of life and new information on the metabolic potential of the microbial world.

With an evolutionary framework of the microbial world in place, and with powerful new methods in hand to guide future research, advances in microbial diversity are happening quickly. Besides unveiling the previously hidden concept of three evolutionary

domains of life, the contributions of Carl Woese and his associates have given microbiologists the tools they need to understand and explore the diversity of our microbial world. In the chapters that follow we will learn how microbiologists have unraveled many of the basic principles that govern living systems, how microorganisms control essential processes that sustain our biosphere, and how we can apply the lessons of microbiology to combat disease and improve our world.

Check Your Understanding

- What kinds of evidence support the three-domain concept of life?
- What is a phylogenetic tree?
- List three reasons why rRNA genes are suitable for phylogenetic analyses.

(a) Cultivation-independent analysis of rRNA genes

(b) Revealing the extent of microbial diversity

Figure 1.42 Analysis of environmental rRNA genes leads to discovery of new microbial species. (a) Norman Pace in 1985 described the first approach to sequence rRNA genes obtained directly from the environment without the need to grow microbes by cultivation in the laboratory. (b) Cultivation-independent analysis of microbial communities in environmental samples has revealed a tremendous diversity of microbial species. The application of cultivation-independent methods has been facilitated greatly by improvements in DNA sequencing technology over time. The graph shows the discovery over time of 16S rRNA gene sequences from natural samples that represent unique microbial species (data adapted from Schloss, P.D., et al. *mBio* 6: doi.org/10.1128/mBio.00201-16).

CHAPTER REVIEW

I • Exploring the Microbial World

- 1.1** Microorganisms are single-celled microscopic organisms that are essential for the well-being and functioning of other life forms and the planet. The tools of microscopy, microbial cultivation, molecular biology, and genomics are cornerstones of modern microbiology.

Q What are bacterial colonies and how are they formed?

- 1.2** Prokaryotic and eukaryotic cells differ in cellular architecture, and an organism's characteristics are defined by its complement of genes—its genome. All cells have a cytoplasmic membrane, a cytoplasm, ribosomes, and a double-stranded DNA genome. All cells carry out activities including metabolism, growth, and evolution.

Q What cellular structures distinguish prokaryotic and eukaryotic cells? What are some differences between a cell wall and a cytoplasmic membrane? In what types of organisms would you expect to find these structures?

- 1.3** Prokaryotic cells, while typically smaller than eukaryotic cells, can range widely in size and morphology. The most common shapes of prokaryotic cells are rods, cocci, and spirilla, and while most bacteria are 0.5 to 10 μm in length, some can be more than 600 μm long.

Q How do diffusion and surface-to-volume (S/V) ratio influence the size and shape of prokaryotic cells?

- 1.4** *Bacteria*, *Archaea*, and *Eukarya* are the major phylogenetic lineages (domains) of cells. The greatest diversity of microorganisms is found in the *Bacteria*, while many extremophiles are found within the *Archaea*. Microbial eukaryotes can vary tremendously in size, with some species being smaller than bacteria. Viruses are acellular and because of this cannot be placed on the tree of life.

Q What features (or lack of features) can be used to distinguish between viruses, *Bacteria*, *Archaea*, and *Eukarya*?

- 1.5** Diverse microbial populations were widespread on Earth for billions of years before plants and animals appeared. Microbes are abundant in the biosphere, and their activities greatly affect the chemical and physical properties of their habitats.

Q Why can Earth, in many ways, be considered a microbial planet? Which event in Earth's history eventually lead to the evolution of multicellular life forms?

- 1.6** Microorganisms can be both beneficial and harmful to humans, although many more microorganisms are beneficial (or even essential) than are harmful. Agriculture, food, energy, and the environment are all affected in major ways by microorganisms.

Q The gut microbiome directly benefits humans by digesting complex carbohydrates and synthesizing vitamins and other nutrients. In what other ways do microorganisms benefit humans?

II • Microscopy and the Origins of Microbiology

- 1.7** Microscopes are essential for studying microorganisms. Bright-field microscopy, the most common form of microscopy, employs a microscope with a series of lenses to magnify and resolve the image. The limit of resolution for a light microscope is about 0.2 μm .

Q What is the difference between magnification and resolution? Can either increase without the other?

- 1.8** An inherent limitation of bright-field microscopy is the lack of contrast between cells and their surroundings. This problem can be overcome by the use of stains or by alternative forms of light microscopy, such as phase contrast or dark field.

Q What is the function of staining in light microscopy? What is the advantage of phase-contrast microscopy over bright-field microscopy?

- 1.9** Differential interference contrast (DIC) microscopy and confocal scanning laser microscopy allow enhanced three-dimensional imaging or imaging through thick specimens.

Q How is confocal scanning laser microscopy different from fluorescence microscopy? In what ways are they similar? How does differential interference contrast microscopy differ from bright-field microscopy?

- 1.10** Electron microscopes have far greater resolving power than do light microscopes, the limits of resolution being about 0.2 nm. The two major forms of electron microscopy are transmission, used primarily to observe internal cell structure, and scanning, used to examine the surface of specimens.

Q Why does an electron microscope have a higher resolution, or greater resolving power, than a light microscope?

III • Microbial Cultivation Expands the Horizon of Microbiology

- 1.11** Louis Pasteur devised ingenious experiments proving that living organisms cannot arise spontaneously from nonliving matter. Pasteur introduced many concepts and techniques central to the science of microbiology, including sterilization, and developed a number of key vaccines for humans and other animals.

Q Explain the principle behind the Pasteur flask in studies on spontaneous generation. Why were the results of this experiment inconsistent with the theory of spontaneous generation?

- 1.12** Robert Koch developed a set of criteria called Koch's postulates for linking cause and effect in infectious diseases. Koch also developed the first reliable and reproducible means for obtaining and maintaining microorganisms in pure culture.

Q What are Koch's postulates and how did they influence the development of microbiology? Why are Koch's postulates still relevant today?

- 1.13** Martinus Beijerinck and Sergei Winogradsky explored soil and water for microorganisms that carry out important natural processes, such as nutrient cycling and the biodegradation of particular substances. Out of their work came the enrichment culture technique and the concepts of chemolithotrophy and nitrogen fixation.

Q What were the major microbiological interests of Martinus Beijerinck and Sergei Winogradsky? It can be said that both men discovered nitrogen fixation. Explain.

IV • Molecular Biology and the Unity and Diversity of Life

- 1.14** All cells share certain characteristics, and microorganisms are used as model systems to explore the fundamental processes that define life. The discoveries of DNA as the molecular basis of heredity, and of its structure and function, paved the way for progress in molecular genetics, microbial phylogeny, and genomics.

Q Describe the experiments that proved DNA to be the molecule at the basis of heredity.

- 1.15** Carl Woese discovered that ribosomal RNA (rRNA) sequences can be used to determine the evolutionary history of microorganisms, and in so doing, he constructed a modern phylogenetic tree of life that revealed a new domain, the *Archaea*. Analysis of rRNA sequences from the environment has shown that microbial diversity is exceptional and that the majority of microorganisms have not yet been cultivated.

Q What insights led to the reconstruction of the tree of life? Which domain, *Archaea* or *Eukarya*, is more closely related to *Bacteria*? What evidence is there to justify your answer?

APPLICATION QUESTIONS

- Pasteur's experiments on spontaneous generation contributed to the methodology of microbiology, understanding of the origin of life, and techniques for the preservation of food. Explain briefly how Pasteur's experiments affected each of these topics.
- Describe the lines of proof Robert Koch used to definitively associate the bacterium *Mycobacterium tuberculosis* with the disease tuberculosis. How would his proof have been flawed if

any of the tools he developed for studying bacterial diseases had not been available for his study of tuberculosis?

- Imagine that all microorganisms suddenly disappeared from Earth. From what you have learned in this chapter, why do you think that animals would eventually disappear from Earth? Why would plants disappear? By contrast, if all higher organisms suddenly disappeared, what in Figure 1.10a tells you that a similar fate would not befall microorganisms?

CHAPTER GLOSSARY

Aseptic technique a series of steps taken to prevent contamination of laboratory cultures and media

Cell wall a rigid layer present outside the cytoplasmic membrane; it confers structural strength on the cell

Chemolithotrophy a form of metabolism in which energy is generated from the oxidation of inorganic compounds and carbon is obtained typically from CO₂

Chromosome a genetic element, usually circular in prokaryotic cells, carrying genes essential to cellular function

Colony a macroscopically visible population of cells growing on solid medium, arising from a single cell

Contrast the ability to resolve a cell or structure from its surroundings

Culture a collection of microbial cells grown using a nutrient medium

Cytoplasm the fluid portion of a cell, enclosed by the cytoplasmic membrane

Cytoplasmic membrane a semipermeable barrier that separates the cell interior (cytoplasm) from the environment

Differentiation modification of cellular components to form a new structure, such as a spore

Domain one of the three main evolutionary lineages of cells: the *Bacteria*, the *Archaea*, and the *Eukarya*

DNA replication the process by which information from DNA is copied into a new strand of DNA

Enrichment culture a culture that employs highly selective laboratory methods for obtaining microorganisms from natural samples

Enzyme a protein (or in some cases an RNA) catalyst that functions to speed up chemical reactions

Eukaryotic having a membrane-enclosed nucleus and various other membrane-enclosed organelles; cells of *Eukarya*

Evolution a change over time in gene sequence and frequency within a population of organisms, resulting in descent with modification

Extremophiles microorganisms that inhabit environments characterized by extremes of temperature, pH, pressure, or salinity

Genome the total complement of genes contained in a cell or virus

Gram-negative a bacterial cell with a cell wall containing small amounts of peptidoglycan and an outer membrane

Gram-positive a bacterial cell whose cell wall consists chiefly of peptidoglycan; it lacks the outer membrane of gram-negative cells

Gram stain a differential staining procedure that stains cells either purple (gram-positive cells) or pink (gram-negative cells)

Growth in microbiology, an increase in cell number with time

Gut microbiome the microbial communities present in the animal gastrointestinal tract

Horizontal gene transfer the unidirectional transfer of genes between cells through a process uncoupled from reproduction

Intercellular communication interactions between cells using chemical signals

Koch's postulates a set of criteria for proving that a given microorganism causes a given disease

Macromolecules a polymer of monomeric units, for example proteins, nucleic acids, polysaccharides, and lipids

Magnification the optical enlargement of an image

Medium (plural, media) in microbiology, the liquid or solid nutrient mixture(s) used to grow microorganisms

Metabolism all biochemical reactions in a cell

Microbial community two or more populations of cells that coexist and interact in a habitat

Microbial ecology the study of the interaction of microorganisms with each other and their environment

Microorganism an organism that is too small to be seen by the unaided human eye

Morphology the physical appearance of a cell as determined by cell shape, for example: rod, coccus, or spirillum

Motility the movement of cells by some form of self-propulsion

Nucleoid the aggregated mass of DNA that makes up the chromosome(s) of prokaryotic cells

Nucleus a membrane-enclosed structure in eukaryotic cells that contains the cell's DNA genome

Organelle a bilayer-membrane-enclosed structure such as the mitochondrion, found in eukaryotic cells

Pathogen a disease-causing microorganism

Phylogenetic tree a diagram that depicts the evolutionary history of an organism; consists of nodes and branches

Phylogeny the evolutionary history of organisms

Plasmid an extrachromosomal genetic element that is usually not essential to the cell

Prokaryotic lacking a membrane-enclosed nucleus and other organelles; cells of *Bacteria* or *Archaea*

Pure culture a culture containing a single kind of microorganism

Resolution the ability to distinguish two objects as distinct and separate when viewed under the microscope

Ribosomal RNA (rRNA) the types of RNA found in the ribosome; some participate actively in protein synthesis

Ribosome a cytoplasmic particle composed of ribosomal RNA and protein, whose function is to synthesize proteins

Spontaneous generation the hypothesis that living organisms can originate from nonliving matter

Sterile free of all living organisms (cells) and viruses

Transcription the synthesis of an RNA molecule complementary to one of the two strands of a double-stranded DNA molecule

Translation the synthesis of protein by a ribosome using the genetic information in a messenger RNA as a template

MICROBIOLOGYNOW

Exploring the Microbial Cell

New microscopic techniques are changing how we view microbial cells. Many cellular processes are performed by macromolecules and structures whose forms dictate their function. These structures are incredibly small and impossible to resolve with standard light microscopy. Cryogenic electron tomography (cryoET) images cells embedded within vitreous ice at ultra-low temperatures so they can be viewed in their native state without dehydration. During cryoET, samples are tilted in an electron microscope and images made at many different angles, much in the same way that a CT scan images a human body. These images are integrated using computer algorithms to generate complex, high-resolution, three-dimensional images that provide unprecedented structural detail. CryoET images have led to the discovery of new features within microbial cells and stunning new insights on well-known structures.

"*Candidatus Pelagibacter ubique*," one of the most abundant organisms on Earth, lives in microbial communities suspended in the upper waters of oceans worldwide. Cells of *Pelagibacter* are quite small (about 0.8 μm long), but their

structures are readily visualized by cryoET (see image). Colors in the cryoET reconstruction indicate the outer membrane (blue), cytoplasmic membrane (cyan), peptidoglycan (white), cytoplasm (orange), nucleoid (red), and ribosomes (yellow). These new images reveal that the periplasm (the space between inner and outer membrane) in these cells is larger than expected and can occupy a remarkable 50–70% of cell volume in nongrowing cells. These images also reveal that the cytoplasm is divided into distinct regions that contain either nucleoid or ribosomes. Finally, mysterious structures such as membrane vesicles have been observed on the extracellular surface of the outer membrane and tethered to the cytoplasmic membrane (not shown). The function of these vesicles is unknown. New imaging techniques such as cryoET move microbiology forward and are revealing surprising complexity and diversity in the structures of prokaryotic cells.

Zhao, X., et al. 2017. Three-dimensional structure of the ultraoligotrophic marine bacterium "*Candidatus Pelagibacter ubique*." *Appl. Environ. Microbiol.* 83: e02807-16.

In this chapter, we consider the structure and function of microbial cells, both prokaryotic and eukaryotic. We will explore the components of microbial cells that control nutrient transport and cellular integrity but also several internal structures, which can be found in certain cells. We will also examine structures that give microbial cells the ability to move within their environment. We begin with two critical cell structures—the cytoplasmic membrane and cell wall—that collectively compose the cell envelope.

I • The Cell Envelope

The cytoplasm of the prokaryotic cell is surrounded by several layers that include a membrane, a cell wall, and other structures specific to the kind of cell. Collectively, these layers form the cell envelope and are essential for preserving the integrity and functioning of the cell.

The **cell envelope** consists of a series of layered structures that surround the cytoplasm and govern cellular interactions with the external environment. The cell envelope has many important functions: It governs transport of nutrients into the cell and wastes out of the cell, it is the site of energy conservation, it governs cell shape, it protects the cell from mechanical stress, and it can help the cell attach to surfaces and even protect the cell from attack.

The diversity of microorganisms is in part reflected in the composition of the cell envelope; but we will also learn that certain

envelope structures are highly conserved and that knowledge of cell envelope structure can help us to identify and classify microorganisms. In the first few sections, we will learn about major components of cell envelope structure including the *cytoplasmic membrane*, *cell wall*, *outer membrane*, and *S-layers*. We start our tour by considering the cytoplasmic membrane, a structure found in all cells.

2.1 The Cytoplasmic Membrane

The **cytoplasmic membrane** surrounds the *cytoplasm*—the mixture of macromolecules and small molecules inside the cell—and separates it from the environment. The cytoplasmic membrane is physically rather weak but is an ideal structure for its major cellular function: selective permeability. In order for a cell to grow, nutrients must be transported inwards and waste products outwards. Both of these events occur across the cytoplasmic membrane. A variety of proteins located in the cytoplasmic membrane facilitate these reactions, and many other membrane proteins play important roles in energy metabolism.

Bacterial Cytoplasmic Membranes

The cytoplasmic membrane of all bacterial and eukaryal cells is a phospholipid bilayer containing embedded proteins. The cytoplasmic membrane is only 8–10 nanometers wide but can be resolved easily by transmission electron microscopy (**Figure 2.1a**). Phospholipids are composed of both hydrophobic (water-repelling) and

Figure 2.1 Phospholipid bilayer membrane. (a) Transmission electron micrograph of a cell with membrane region shown in detail. (b) General architecture of a bilayer membrane; phospholipids are composed of a hydrophilic head group (blue spheres) with fatty acid tails (yellow lines). The phospholipid head groups of the bilayer are visible in a as parallel dark lines, between which can be found a lighter region comprising the hydrophobic region of the membrane. (c) Structure of the phospholipid phosphatidylethanolamine. Each fatty acid side chain is connected to the head group by an ester bond (boxed with a red dashed line); ester linkages are a characteristic feature of lipids from *Bacteria* and *Eukarya* but not those of *Archaea*.

hydrophilic (water-attracting) components (Figure 2.1b). In *Bacteria* and *Eukarya*, the hydrophobic component consists of fatty acid “tails” and the hydrophilic component consists of a glycerophosphate (a glycerol molecule bound to a phosphate) and one of several other functional groups (such as sugars, ethanolamine, or choline) also bonded to the phosphate (Figure 2.1c). The membrane is comprised of two phospholipid layers in which the fatty acid tails associate together to form a hydrophobic region, leaving the hydrophilic “head groups” exposed to either the environment or the cytoplasm (Figure 2.1b). That is, the *outer* surface of the cytoplasmic membrane faces the environment while the *inner* surface faces the cytoplasm and interacts with the cytoplasmic milieu. This type of membrane structure is called a *lipid bilayer*, or a *unit membrane*.

A variety of proteins are attached to or integrated into the cytoplasmic membrane; membrane proteins typically have hydrophobic domains that span the membrane and hydrophilic domains that contact the environment or the cytoplasm (Figure 2.2). Proteins significantly embedded in the membrane are called *integral* membrane proteins. Many, though not all, integral membrane proteins extend completely across the membrane, and these are called *transmembrane* proteins. By contrast, *peripheral* membrane proteins are more loosely attached. Some peripheral membrane proteins are lipoproteins, proteins that contain a hydrophobic lipid tail that anchors the protein into the membrane. Other peripheral membrane proteins have residues that associate with the hydrophilic head groups of

phospholipids, or they associate indirectly with membranes by binding to other proteins anchored in the membrane. Peripheral membrane proteins typically interact with integral membrane proteins in important cellular processes such as energy metabolism and transport.

Archaeal Cytoplasmic Membranes

The cytoplasmic membrane of *Archaea* is structurally similar to those of *Bacteria* and *Eukarya*, but the chemistry is somewhat different. In the lipids of *Bacteria* and *Eukarya* the hydrophobic *fatty acid* tails are bound to glycerol by *ester* linkages (Figure 2.1); in contrast, the lipids of *Archaea* have hydrophobic *isoprenoid* (rather than fatty acid) tails, which are bound to glycerol by *ether* bonds (Figure 2.3). The hydrophobic region of archaeal membranes is formed from repeating units of the five-carbon hydrocarbon *isoprene*, rather than from fatty acids (compare Figures 2.1 and 2.3).

The cytoplasmic membrane of *Archaea* is constructed from either phosphoglycerol diethers, which can have C_{20} side chains (called a *phytanyl* group), or diphosphoglycerol tetraethers (C_{40} side chains, called a *biphytanyl* group) (Figure 2.3). In the tetraether lipid structure, the ends of the inwardly pointing isoprenoid chains are covalently linked at their termini to form a *lipid monolayer* (Figure 2.3c) instead of a lipid bilayer (Figure 2.3a) membrane.

Archaeal lipids can have many different isoprenoid chains including some that contain ring structures. For example, *crenarchaeol*, a

Figure 2.2 Structure of the cytoplasmic membrane. The inner surface (**In**) faces the cytoplasm and the outer surface (**Out**) faces the environment. Phospholipids compose the matrix of the cytoplasmic membrane with proteins embedded (integral) or surface associated (peripheral). The general design of the cytoplasmic membrane is similar in both prokaryotic and eukaryotic cells, although there can be differences in the chemistry between different species. Note that this membrane is shown in a relaxed shape to better illustrate its inner and outer surfaces; in a living cell, cytoplasmic turgor pressure would cause the membrane to have convex curvature.

Figure 2.3 Major lipids of *Archaea* and the architecture of archaeal membranes. (a, b) *Archaea* can have lipid bilayers composed of phosphoglycerol diether lipids. The hydrophobic portions of archaeal lipids are comprised of isoprenoid chains synthesized from repeated units of isoprene (in dashed red ovals); this contrasts with the lipids of *Bacteria* and *Eukarya*, which have fatty acid tails (Figure 2.1). Note that these isoprenoids are bonded to glycerol by an ether linkage (in dashed red box). (b, c) Some *Archaea* can also have lipid monolayers composed of diposphoglycerol tetraether lipids or other isoprenoid lipids such as crenarchaeol. The isoprenoid lipids in b are phytanyl (C_{20}), biphytanyl (C_{40}), and crenarchaeol. Isoprene lipids can often contain 5- and 6-carbon rings such as those present in crenarchaeol. The membrane structure in *Archaea* may form a lipid bilayer or a lipid monolayer (or a mix of both).

common membrane lipid in cells of *Thaumarchaeota* (a major phylum of *Archaea*, ► Section 17.5) contains four C_5 rings and one C_6 ring (Figure 2.3b). These rings affect the chemical properties of the lipids and thus influence membrane function. As in other organisms, the polar head groups in archaeal lipids can be sugars, ethanolamine, or a variety of other molecules.

Despite differences in chemistry between the cytoplasmic membranes of *Archaea* and organisms in the other phylogenetic domains, the fundamental construction of the archaeal cytoplasmic membrane—inner and outer hydrophilic surfaces and a hydrophobic interior—is the same as that of membranes in all cells. Obviously, evolution has selected this fundamental design as the best solution to the major functions of the cytoplasmic membrane, an issue we turn to now.

Cytoplasmic Membrane Function

The cytoplasmic membrane has at least *three* major functions (Figure 2.4). First, it is the cell's permeability barrier, preventing the passive leakage of solutes into or out of the cell. Second, the cytoplasmic membrane anchors several proteins that catalyze a suite of

key cell functions. And third, the cytoplasmic membrane of *Bacteria* and *Archaea* plays a major role in energy conservation and consumption.

The cytoplasmic membrane is a barrier to the diffusion of most substances, especially polar or charged molecules. Because the cytoplasmic membrane is so impermeable, most substances that enter or leave the cell must be carried in or out by *transport proteins*. These are not simply ferrying proteins but instead function to *accumulate* solutes against the concentration gradient, a process that diffusion alone cannot do (Figure 2.5). Transport, which requires energy, ensures that the cytoplasm has sufficient concentrations of the nutrients it needs to perform biochemical reactions efficiently.

Transport proteins typically display high sensitivity and high specificity. If the concentration of a solute is high enough to saturate the transporter, which often occurs at the very low concentrations of nutrients found in nature, the rate of uptake can be near maximal (Figure 2.5). Some nutrients are transported by a low-affinity transporter when the nutrient is present at *high* external concentration and by a separate, typically higher-affinity, transporter when the nutrient is present at *low* concentration (Figure 2.5).

Functions of the cytoplasmic membrane

Figure 2.4 The major functions of the cytoplasmic membrane. Although physically weak, the cytoplasmic membrane controls at least three critically important cellular functions: maintaining selective permeability, anchoring proteins, and conserving energy.

Moreover, many transport proteins transport only a single kind of molecule while others carry a related class of molecules, such as different sugars or different amino acids. This economizing reduces the need for separate transport proteins for each different sugar or amino acid.

In addition to its permeability and transport functions, the cytoplasmic membrane of *Bacteria* and *Archaea* is a major site of both energy conservation and energy consumption. We discuss in Chapter 3 how the cytoplasmic membrane can be energized when protons (H⁺) are separated from hydroxyl ions (OH⁻) across the membrane surface (Figure 2.4c). This charge separation creates an energized state of the membrane called the *proton motive force*, analogous to the potential energy present in a charged battery. Dissipation of the proton motive force can be coupled to several energy-requiring reactions, such as transport, cell locomotion, and the biosynthesis of ATP. In eukaryotic microbial cells, although transport across the cytoplasmic membrane is just as necessary as it is in prokaryotic cells, energy conservation takes place in the membrane systems of the cell's key organelles, the mitochondrion (respiration) and chloroplast (photosynthesis), as we will see later in this chapter.

Figure 2.5 The importance of transport in membrane function. In both types of transport, the uptake rate shows saturation at relatively low external solute concentrations. Both high-affinity and low-affinity transport systems are depicted.

Check Your Understanding

- Draw the basic structure of a lipid bilayer and label the hydrophilic and hydrophobic regions. Why is the cytoplasmic membrane a good permeability barrier?
- How are the membrane lipids of *Bacteria* and *Archaea* similar, and how do they differ?
- Describe the major functions of the cytoplasmic membrane.
- Which molecule types can pass through the phospholipid bilayer directly by simple diffusion?

2.2 Transporting Nutrients into the Cell

In Section 2.1 we learned how the structure of the cytoplasmic membrane is an effective barrier to leakage; solutes leak neither into nor out of a living cell. However, selective transport is a major function of the cytoplasmic membrane. In order for cells to survive and grow, they must transport nutrients across the membrane and into the cell and they must export wastes out of the cell. Substances are transported across the cytoplasmic membrane through membrane-spanning integral membrane proteins (Figure 2.2). Some transporters also require the action of peripheral membrane proteins. We consider the most common of these transport systems here, with a focus on the well-studied transporters widespread in *Bacteria* and *Archaea*.

Active Transport and Transporters

Active transport is the process by which cells accumulate solutes against the concentration gradient. Three basic mechanisms of active transport are found in prokaryotic cells. A **simple transport system** consists only of a transmembrane transport protein, **group translocation** employs a series of proteins in the transport event, and **ABC transport systems** consist of three components: a binding protein, a transmembrane transporter, and an ATP-hydrolyzing protein (Figure 2.6). Each of these transport systems is energy-driven, be it from the proton motive force, ATP, or some other energy-rich compound.

The transmembrane component of virtually all transport systems is composed of a polypeptide containing 12 regions (called *domains*) that weave back and forth through the membrane to form a channel, and it is through this channel that the solute is transported into

Figure 2.6 The three classes of transport systems. Transmembrane transporters are generally composed of a polypeptide that has 12 α -helices (each shown as a cylinder) that aggregate to form a channel through which solutes can cross the membrane. In simple transport the movement of a solute is coupled with the dissipation of an electrochemical gradient such as the proton motive force. ABC transporters have three components: a binding protein that has high affinity for

a substrate, a transmembrane protein channel, and a cytoplasmic ATP-hydrolyzing protein, which supplies the energy required to drive substrate transport. In group translocation, the substance transported is chemically modified upon entering the cell. For example, the glucose group translocation system has five proteins: Enzyme (Enz) I, Enzymes II_a, II_b, and II_c, and HPr. A phosphate cascade occurs from phosphoenolpyruvate (PEP) to Enz II_c, and the latter protein actually

transports and simultaneously phosphorylates the sugar. Proteins HPr and Enz I are nonspecific and participate in the transport of any sugar, while the three components of Enz II are specific for a particular sugar. Note how simple transporters and the ABC system transport substances without chemically modifying them, whereas group translocation results in chemical modification (in this case phosphorylation) of the transported substance.

the cell. Transport is linked to a conformational change in this transmembrane protein complex that occurs when it binds its specific solute. Like a gate swinging open, this conformational change sweeps the solute into the cell.

Simple Transporters and Group Translocation

Simple transport reactions are driven by the energy inherent in the proton motive force (Figure 2.4c). The two major transport events catalyzed are either *symport* reactions (where a solute and a proton are cotransported in the same direction) or *antiport* reactions (where a solute and a proton are transported in opposite directions) (Figure 2.6). A classic example of a simple transporter is the uptake of the sugar lactose by way of the *lac permease*, a well-studied symporter in *Escherichia coli*. As each lactose molecule enters the cell, the potential energy in the proton motive force is diminished slightly by the cotransport of a proton (Figures 2.4c and 2.6). The net result is the energy-driven accumulation of lactose in the cytoplasm against the concentration gradient. Many other solutes enter by the activity

of their own simple symporters, including phosphate, sulfate, and several different organic compounds.

Group translocation differs from simple transport in two important ways: (1) the transported substance is *chemically modified* during the transport process, and (2) an energy-rich organic compound (rather than the proton motive force) drives the transport event. The best-studied group translocation systems transport the sugars glucose, mannose, and fructose in *E. coli*. During uptake, these compounds are phosphorylated by the *phosphotransferase system* (Figure 2.6). The phosphotransferase system consists of a family of five proteins that work in concert to transport any given sugar. Before the sugar is transported, the proteins in the phosphotransferase system are themselves alternately phosphorylated and dephosphorylated in a cascading fashion until Enzyme II_c phosphorylates the sugar as it enters the cytoplasm (Figure 2.6). A protein called HPr, the enzyme that phosphorylates HPr (Enzyme I), and Enzyme II_a are all cytoplasmic proteins. By contrast, Enzyme II_b is a peripheral membrane protein and Enzyme II_c is the transmembrane component.

In the phosphotransferase system, HPr and Enzyme I are *nonspecific* components and participate in the uptake of several different sugars. By contrast, distinct Enzyme II proteins exist, one set for each different sugar transported. Energy to drive the phosphotransferase system comes from phosphoenolpyruvate, an energy-rich intermediate in glycolysis (► Sections 3.4 and 3.6).

ABC Transporter Systems

ABC transporters are modular systems that have three components: a binding protein, a transmembrane protein channel, and an ATP-hydrolyzing protein (Figure 2.6). The ABC stands for ATP-binding cassette, a structural feature of proteins that bind ATP. More than 200 different ABC transport systems are known, and these catalyze the uptake of a wide variety of organic and inorganic compounds.

Substrate-binding proteins are present outside of the cell, where they bind to a specific substrate and enable its transport into the cell. A characteristic property of binding proteins is their extremely high substrate affinity. These proteins can bind their specific substrate even when it is present at extremely low concentration; for example, less than 1 micromolar (10^{-6} M). Once its specific substrate is bound, the binding protein interacts with its respective transmembrane component to transport the substrate into the cell driven by the energy in ATP (Figure 2.6).

We move on now from our coverage of the cytoplasmic membrane to consider components of the cell envelope that confer structural strength on the cell, something the membrane cannot do.

Check Your Understanding

- Which major characteristic of ABC transport systems makes them ideal for organisms living in nutrient-poor environments?

2.3 The Cell Wall

The cytoplasm of prokaryotic cells maintains a high concentration of dissolved solutes that creates significant osmotic pressure—about 2 atm (203 kPa); this is about the same as the pressure in an automobile tire. This osmotic pressure is sufficient to cause the cell membrane to burst and the cell to die—a process called *cell lysis*. To withstand this *turgor pressure*, the cell envelopes of most *Bacteria* and *Archaea* have a layer outside the cytoplasmic membrane called the *cell wall*. Besides protecting against osmotic lysis, cell walls also maintain cell shape and rigidity.

The cell envelopes of most *Bacteria* can be classified as being either *gram-positive* or *gram-negative* based on their organization and cell wall structures. The structures of gram-positive and gram-negative cell envelopes differ markedly as viewed in the electron microscope (Figure 2.7). The cell envelope of a gram-positive cell typically contains a cytoplasmic membrane and a thick cell wall, whereas a gram-negative cell has a cytoplasmic membrane, a thin cell wall, an outer membrane (Figure 2.7), and a periplasm, which is a compartment between the cytoplasmic and outer membranes.

We will consider the outer membrane and periplasm in the next section. The names we use to describe the typical gram-positive and gram-negative cell envelopes are based on their Gram stain reactions (◀ Section 1.8). The Gram stain reaction is determined primarily by the thickness of the cell wall rather than the number of layers in the cell envelope, and so Gram stain reaction does not always correlate with cell envelope structure. However, the Gram stain reaction is sufficiently predictive of cell envelope structure in *Bacteria* that the names of the two most common bacterial cell envelopes—gram-positive and gram-negative—are based on their typical reactions to the Gram stain.

Knowledge of cell wall envelope structure and function is important not only for understanding the biology of microbial cells but also for medical reasons. Certain antibiotics, for example, the penicillins and cephalosporins, target bacterial cell wall synthesis, leaving the cell susceptible to osmotic lysis. Since human and other animal cells lack cell walls and are therefore not a target of such antibiotics, these drugs are of obvious benefit for treating bacterial infections. The major component of the bacterial cell wall, and a target of many antibiotics, is a molecule called *peptidoglycan*, and we consider this molecule in detail now.

Bacterial Cell Walls

The cell walls found in *Bacteria* contain a rigid polysaccharide called **peptidoglycan** that confers structural strength on the cell. Peptidoglycan is found in all *Bacteria* that contain a cell wall, but it is unique to *Bacteria* and is not found in *Archaea* or *Eukarya*. The sugar backbone of peptidoglycan is composed of alternating repeats of two modified glucose residues called *N-acetylglucosamine* and *N-acetylmuramic acid* joined by a β -1,4 linkage (Figure 2.8). Attached to the latter residue is a short peptide side chain. The amino acid composition of this peptide side chain can vary considerably between bacterial species. In *Escherichia coli* this peptide contains the amino acids L-alanine, D-alanine, D-glutamic acid, and diaminopimelic acid (DAP), though in other bacteria, L-lysine can be substituted for DAP. The presence of D stereoisomer amino acids, D-alanine and D-glutamic acid, is an unusual feature of peptidoglycan since proteins are always constructed of L-amino acids. These constituents are connected in an ordered way to form the *glycan tetrapeptide* (Figure 2.8), and long chains of this basic unit form peptidoglycan.

Strands of peptidoglycan run parallel to each other around the circumference of the cell (Figure 2.9). The peptide side chains of adjacent peptidoglycan strands are cross-linked together by covalent peptide bonds (Figure 2.9a), and in this way, the peptidoglycan forms one single enormous molecule. In gram-negative bacteria, the cross-links form primarily between the amino group of DAP on one glycan strand and the carboxyl group of the terminal D-alanine on the adjacent glycan strand (Figure 2.9a). The cell wall in the gram-negative cell envelope is 2–7 nm thick consisting primarily of a single layer of peptidoglycan, though it can be up to three layers thick in some places (Figure 2.9c). The peptidoglycan mesh so formed is flexible and porous, but strong enough to resist turgor pressure and prevent rupture of the cytoplasmic membrane and cell lysis. Additional strength against osmotic lysis in gram-negative bacteria is provided by the outer membrane, as discussed in the next section.

Figure 2.7 Cell envelopes of *Bacteria*. (a, b) Schematic diagrams of gram-positive and gram-negative cell envelopes; the Gram stain procedure was described in Section 1.8 and shown in Figure 1.23. The photo of Gram-stained bacteria in the center shows cells of *Staphylococcus aureus* (purple, gram-positive) and *Escherichia coli* (pink, gram-negative). (c, d) Transmission electron micrographs showing the cell wall of a gram-positive bacterium and a gram-negative bacterium, respectively. (e, f) Scanning electron micrographs of gram-positive and gram-negative bacteria, respectively. Note differences in surface texture. Each cell is about 1 μm wide.

The typical bacterial gram-positive cell envelope contains a thick peptidoglycan cell wall, which can measure 20 to 35 nm in thickness and is usually much thicker than the wall of gram-negative organisms. As much as 90% of the gram-positive cell envelope can consist of peptidoglycan. Whereas the gram-negative cell wall typically contains only a single layer of peptidoglycan, the gram-positive cell wall can be 15 or more layers thick (Figure 2.10a). The peptidoglycan of

the gram-positive cell wall is stabilized three-dimensionally by peptide cross-links, which form between adjacent peptidoglycan strands both horizontally and vertically. In gram-positive bacteria, peptide cross-links often contain a short peptide “interbridge,” the kinds and numbers of amino acids in the interbridge varying between species. In the gram-positive bacterium *Staphylococcus aureus*, for example, the interbridge often consists of five glycines (Figure 2.9b).

Figure 2.8 Structure of the repeating unit in peptidoglycan, the glycan tetrapeptide. The structure given is that for the peptidoglycan of *Escherichia coli* and most other gram-negative *Bacteria*. Cross-links can be formed between adjacent peptide side chains at residues having free amino and carboxyl groups (circled in blue). For example, cross-links in *E. coli* most commonly occur between the amino group of diaminopimelic acid on one peptide and the terminal carboxyl group of D-alanine on a different peptide.

Figure 2.12c
Parts of the
Gram-positive
cell wall

In addition to peptidoglycan, many gram-positive bacteria produce acidic molecules called **teichoic acids** embedded in their cell wall (Figure 2.10). Teichoic acids are composed of glycerol phosphate or ribitol phosphate with attached molecules of glucose or D-alanine (or both). Individual alcohol molecules are then connected through their phosphate groups to form long strands, and these are then covalently linked to peptidoglycan (Figure 2.10b). Some teichoic acids are covalently bonded to membrane lipids rather than to peptidoglycan, and these are called **lipoteichoic acids**.

Peptidoglycan can be destroyed by **lysozyme**, an enzyme that cleaves the glycosidic bond between N-acetylglucosamine and N-acetylmuramic acid (Figure 2.8). This weakens the peptidoglycan and can cause cell lysis. Lysozyme is present in human secretions including tears, saliva, and other bodily fluids, and functions as a major line of defense against bacterial infection. Many antibiotics, including penicillin, also target peptidoglycan. Whereas lysozyme destroys preexisting peptidoglycan, penicillin blocks the formation of peptide cross-links, which compromises the strength of the peptidoglycan, leading to cell lysis.

Archaeal Cell Walls

The cell envelopes of *Archaea* differ in fundamental ways from those of *Bacteria*. We have already learned that the cytoplasmic membranes of *Archaea*, while functionally analogous to those of *Bacteria*, differ in chemical structure (Section 2.1). Another major difference

Figure 2.9 Peptidoglycan structure in the cell wall. (a) Gram-negative cells that have thin cell walls, such as the cell wall of *E. coli*, mostly have direct cross-links between peptide side chains. (b) Gram-positive cells that have thick cell walls, such as *S. aureus*, can also have peptide interbridges that extend between cross-linked peptide side chains. (c) Conformation of peptidoglycan in the gram-negative cell wall. G, N-acetylglucosamine; M, N-acetylmuramic acid. Note how glycosidic bonds confer strength on peptidoglycan around the circumference of the cell whereas peptide bonds confer strength along the axis of the cell.

is that *Archaea* lack peptidoglycan. In addition, *Archaea* typically lack an outer membrane (see Section 2.4). One consequence of these differences is that the Gram stain reaction is not very useful for predicting the structures of archaeal cell envelopes and so we typically do not use the terms gram-positive and gram-negative to describe cells of *Archaea*. Most *Archaea* lack a polysaccharide-containing cell wall and instead have an *S-layer* (see Section 2.5), which is a rigid protein shell that functions to prevent osmotic lysis just as does the bacterial cell wall.

While some *Archaea* do have cell walls, these walls have unique chemical structures not found in *Bacteria*. For example, the cell walls of certain methane-producing *Archaea* (methanogens) contain a polysaccharide called **pseudomurein** (Figure 2.11), which is structurally remarkably similar to peptidoglycan (the term *murein* is from the Latin word for “wall” and was an old term for peptidoglycan). The backbone of pseudomurein is formed from alternating repeats

Figure 2.10 Structure of the gram-positive bacterial cell wall. (a) Schematic of a gram-positive cell wall showing the internal architecture of the peptidoglycan and its relationship to teichoic acids. Peptide cross-links form between peptidoglycan strands that are adjacent both horizontally and vertically, and peptidoglycan can also form covalent bonds to teichoic acids. (b) Structure of a ribitol teichoic acid. The teichoic acid is a polymer of the repeating ribitol unit shown here. (c) Summary diagram of the gram-positive bacterial cell wall. Lipoteichoic acids tether the cell wall to the cell membrane.

of *N*-acetylglucosamine (also present in peptidoglycan) and *N*-acetylglucosaminuronic acid; the latter replaces the *N*-acetylmuramic acid of peptidoglycan. Pseudomurein also differs from peptidoglycan in that the glycosidic bonds between the sugar derivatives are β -1,3 instead of β -1,4, and the amino acids are all of the L stereoisomer (compare Figures 2.9 and 2.11).

Because in many respects they are so similar, it is likely that peptidoglycan and pseudomurein are variants of a cell wall polysaccharide originally present in the common ancestor of *Bacteria* and *Archaea*. However, although they are structurally and functionally very similar, they differ sufficiently that pseudomurein is immune from destruction by both lysozyme and penicillin, molecules that destroy peptidoglycan.

Figure 2.11 Pseudomurein. Structure of pseudomurein, the cell wall polymer of *Methanobacterium* species. Note the similarities and differences between pseudomurein and peptidoglycan (Figures 2.8 and 2.9).

Check Your Understanding

- Explain how peptidoglycan's structural arrangement resists turgor pressure.
- Describe the major differences between the cell walls of gram-negative and gram-positive bacteria.
- Explain whether you expect the enzyme lysozyme to be equally effective against *Bacteria* and *Archaea*.

2.4 LPS: The Outer Membrane

Most of the gram-negative cell envelope is composed of the **outer membrane**. The outer membrane is a second lipid bilayer found external to the cell wall (**Figure 2.12**), but its structure and function differs from that of the cytoplasmic membrane. The outer membrane and cytoplasmic membrane are similar in that they both contain phospholipid and protein, but a major difference is that the outer membrane also contains polysaccharide molecules covalently bound to lipids (Figure 2.12). Hence, the outer membrane is often called the **lipopolysaccharide** layer, or simply **LPS** for short.

LPS molecules have several unique functions: They can facilitate surface recognition, they are important virulence factors for some bacterial pathogens, and they contribute to the mechanical strength of the cell. We will see that another major difference between the cytoplasmic and outer membranes is that the outer membrane contains *porins*, which are transmembrane proteins that allow for the nonspecific transport of solutes. Hence, we will see that the outer membrane is far more permeable than is the cytoplasmic membrane.

Structure and Activity of LPS

While the precise chemistry of LPS can vary among different species of bacteria, these molecules have several common features. As seen in **Figure 2.13**, LPS contains a polysaccharide that consists of two

Figure 2.12 The gram-negative bacterial cell envelope. (a) Arrangement of lipopolysaccharide, lipid A, phospholipid, porins, and Braun lipoprotein in the outer membrane. See Figure 2.13 for details of the structure of LPS. (b) Transmission electron micrograph of a cell of *Escherichia coli* showing the cytoplasmic membrane and wall. (c) Molecular model of porin proteins showing their hollow pores that allow solute transport across the outer membrane. The view of the porin is perpendicular to the plane of the membrane. The black dashed circle highlights some of the hydrophilic amino acids that line the inside of the pore.

components, the *core polysaccharide* and the *O-specific polysaccharide* (see also Figure 2.12a). In *Salmonella* species, where LPS has been well studied, the core polysaccharide consists of ketodeoxyoctonate (KDO), various seven-carbon sugars (heptoses), the hexose sugars glucose and galactose, and *N*-acetylglucosamine. Connected to the core is the O-specific polysaccharide, which typically contains galactose, glucose, the hexoses rhamnose and mannose, and one or more dideoxyhexoses, such as abequose, colitose, paratose, or tyvelose. These sugars are connected in four- or five-membered sequences, which often are branched. When the sequences repeat, the long O-specific polysaccharide is formed. Within the outer membrane these negatively charged polysaccharides can be linked together tightly when adjacent LPS molecules mutually form ionic bonds to divalent cations (such as Ca^{2+} and Mg^{2+}). The presence of these ionic bonds confers considerable strength to the outer

membrane, which rivals the gram-negative cell wall in its mechanical strength.

The lipid portion of the LPS, called *lipid A*, is not a typical glycerol lipid (see Figure 2.1c); instead the fatty acids are bonded through the amine groups from a disaccharide composed of glucosamine phosphate. The disaccharide is attached to the core polysaccharide through KDO (Figure 2.13). Fatty acids typically found in lipid A include caproic (C_6), lauric (C_{12}), myristic (C_{14}), palmitic (C_{16}), and stearic (C_{18}) acids. LPS replaces much of the phospholipid in the outer half of the outer membrane, and although the outer membrane is technically a lipid bilayer, its many unique components distinguish it from the cytoplasmic membrane. The outer membrane is anchored to the peptidoglycan layer by the *Braun lipoprotein*, a molecule that spans the gap between the LPS layer and the peptidoglycan layer (in the periplasm, discussed in the next subsection) (Figure 2.12a).

Figure 2.13 Structure of bacterial lipopolysaccharide. The chemical structures of lipid A and polysaccharides can vary among gram-negative *Bacteria*, but the major components (lipid A–KDO–core–O-specific) are typically invariant. The O-specific polysaccharide is highly variable among species. KDO, ketodeoxyoctonate; Hep, heptose; Glu, glucose; Gal, galactose; GluNac, *N*-acetylglucosamine; GlcN, glucosamine; P, phosphate. Glucosamine and the lipid A fatty acids are linked through the amine groups of GlcN. The lipid A portion of LPS can be toxic to animals and comprises the endotoxin complex. Compare the art here with that of Figure 2.12 and follow the LPS components by their color-coding.

An important biological activity of LPS is its toxicity to animals. Common gram-negative pathogens for humans include species of *Salmonella*, *Shigella*, and *Escherichia*, among many others, and some of the gastrointestinal symptoms these pathogens elicit are due to their toxic outer membrane components. Toxicity is specifically linked to the LPS layer, in particular, to lipid A. The term *endotoxin* refers to this toxic component of LPS. Some endotoxins cause violent symptoms in humans, including gas, diarrhea, and vomiting, and the endotoxins produced by *Salmonella* and enteropathogenic strains of *Escherichia coli* transmitted in contaminated foods are classic examples of this. We discuss major gram-negative enteric pathogens in Chapter 33 and endotoxin in Section 25.8.

The Periplasm and Porins

The outer membrane is impermeable to proteins and other very large molecules. In fact, a major function of the outer membrane is to prevent cellular proteins whose activities must occur outside the cytoplasm from diffusing away from the cell. These extracellular proteins reside in the **periplasm**, a space of about 15 nm located between the *outer surface* of the cytoplasmic membrane and the *inner surface* of the outer membrane (Figure 2.12a, b).

The periplasm may contain several different classes of proteins. These include hydrolytic enzymes, which function in the initial degradation of polymeric substances; binding proteins, which begin the process of transporting substrates (Section 2.2 and Figure 2.6); chemoreceptors, which are proteins that govern the chemotaxis response (Section 2.11); and proteins that construct extracellular structures (such as peptidoglycan and the outer membrane) from precursor molecules secreted through the cytoplasmic membrane. Most periplasmic proteins reach the periplasm by way of a protein-exporting system present in the cytoplasmic membrane (► Sections 6.12 and 6.13).

The outer membrane is relatively permeable to small molecules because of proteins called *porins* that function as channels for the entrance and exit of solutes (Figure 2.12a, c). Porins are unique to the outer membrane of *Bacteria* and should not be confused with *aquaporins*, which are a different class of proteins (aquaporins facilitate water transport across the cytoplasmic membrane). Several porins are known, including both specific and nonspecific classes. Nonspecific porins form water-filled channels through which most

very small hydrophilic substances can pass. By contrast, specific porins contain a binding site for one or a group of structurally related substances. Porins are transmembrane proteins composed of three identical polypeptides; the proteins are arranged to form channels through which solutes can diffuse (Figure 2.12c).

While the cell envelopes of many *Bacteria* conform to either the gram-positive or the gram-negative model, we have already learned that *Archaea* have cell envelopes that diverge from both of these model structures. In the next section we will see that there is considerable diversity in cell envelope structure across the microbial world.

Check Your Understanding

- Describe and contrast the cell envelope structure of gram-negative and gram-positive bacteria.
- What is the function of porins, and where are they located in the gram-negative cell envelope?
- What component of the gram-negative cell envelope has endotoxin properties?

2.5 Diversity of Cell Envelope Structure

While many *Bacteria* have a gram-positive or gram-negative cell envelope organization (Figure 2.7), a variety of cell envelope structures are known. One way in which cell envelopes can vary between cells is in the presence of an *S-layer*.

S-Layers

S-layers are found in many *Bacteria* and in nearly all *Archaea*. An S-layer consists of a paracrystalline monolayer of interlocking molecules of protein or glycoprotein (Figure 2.14). When an S-layer is present, it is always the *outermost* layer of the cell envelope (Figure 2.14a). The S-layer is usually composed of only one or a few subunits self-organized into repeating structures, which can have hexagonal, tetragonal, or trimeric symmetry. These repeating units form a rigid yet permeable paracrystalline lattice (Figure 2.14b), which can be as much as 5–20 nm thick in *Bacteria* and up to 70 nm thick in some *Archaea*.

S-layers have many important functions. In many *Archaea*, thick S-layers can take on the role of the cell wall and are responsible for providing structural strength, protecting the cell from osmotic lysis,

(a) The S-layer (SL), outer membrane (OM), peptidoglycan cell wall (CW), and cytoplasmic membrane (CM) can be clearly seen in this electron tomographic slice through a cell of *Caulobacter crescentus*, a stalked bacterium that has a gram-negative cell envelope plus an outer S-layer. (b) Transmission electron micrograph of a portion of an S-layer removed from the bacterium *Aquaspirillum* and flattened to show the paracrystalline nature and hexagonal symmetry common to S-layers. The stalk in *a* has an outer diameter of about 150 nm and both images are at the same scale.

and conferring cell shape. The S-layer can also create a periplasmic-like space in *Archaea*. S-layers function as molecular sieves and have pore sizes in the range of 2–10 nm in diameter. These pores are large enough to allow low-molecular-weight compounds to pass but small enough to trap large molecules—such as most proteins—in the space between the S-layer and the cytoplasmic membrane. The compartment formed between the cytoplasmic membrane and the S-layer thus functions much as the periplasm does in gram-negative bacteria, including forming a site near the cytoplasmic membrane where reactions important to cellular metabolism can occur. As the outermost layer of the cell, S-layers can also facilitate cell surface interactions, such as attachment. S-layers can also increase the ability of some bacterial pathogens to cause disease by either promoting adhesion or protecting the cell from host defenses.

Alternative Configurations of the Cell Envelope

We have now learned about the most common components found in the cell envelope: the cytoplasmic membrane (CM), the cell wall (CW), the outer membrane (OM), and S-layers (SL). While certain configurations of these structures are common, a range of different configurations are possible (Figure 2.15). A common variation on cell envelope structure is to find an outer S-layer surrounding an otherwise gram-positive or gram-negative bacterium (compare Figure 2.15a with Figure 2.15b). In addition, many *Archaea* have only an S-layer outside of their cytoplasmic membrane, and these layers, while always constructed of some type of paracrystalline protein or

(d) *Mycoplasma pneumoniae*

Figure 2.15 Alternative cell envelope structures. Cell envelope structures including cytoplasmic membranes (CM), cell walls (CW), outer membranes (OM), and S-layers (SL) can be found in both bacterial and archaeal species. (a) *Vibrio cholerae* has a classic gram-negative type bacterial cell envelope. (b) *Caulobacter crescentus* is a bacterium with a gram-negative

envelope and an S-layer (see also Figure 2.14a). (c) *Nitrosopumilus maritimus* has a typical archaeal cell envelope containing a CM and an SL. (d) *Mycoplasma pneumoniae* is a pathogenic bacterium whose cell envelope consists of only a CM. S-layers, while typically composed of a paracrystalline protein or glycoprotein layer (see also Figure 2.14b) can vary

considerably in molecular structure (compare the S-layers in *b* and *c*). All images are transmission electron tomographs, a technique in which a special transmission electron microscope passes electrons through a specimen at different angles and then consolidates the views to form a final three-dimensional image.

glycoprotein, can vary considerably in their molecular structures (compare Figure 2.15*b* with Figure 2.15*c*). Some methanogenic *Archaea* also have cell walls made of pseudomurein, and such cell walls may or may not have an outer S-layer as well. Finally, though unusual, *Archaea* such as the heat-loving *Ignicoccus* actually have an outer membrane. This structure in *Ignicoccus* is unlike that of gram-negative bacteria in that it is composed largely of archaeal isoprenoid lipids and lacks LPS.

Although this is uncommon, a few *Bacteria* and *Archaea* lack cell walls altogether. These include in particular the mycoplasmas (Figure 2.15*d*) and other pathogenic *Bacteria* that grow within a host cell, and *Archaea* such as *Thermoplasma* and its relatives. Lacking a cell wall, these cells would be expected to contain unusually tough cytoplasmic membranes, and chemical analyses show that they do. For example, most mycoplasmas contain *sterols* in their cytoplasmic membranes; these molecules function to add strength and rigidity to the membrane as they do in the cytoplasmic membranes of eukaryotic cells. Mycoplasmas may also have little need for a cell wall because they experience little osmotic pressure when living within the cytoplasm of another cell. In addition, the loss of peptidoglycan may help mycoplasmas evade the host immune system because host defenses recognize bacterial cell wall components as one of many signals of bacterial invasion (Chapter 26).

Check Your Understanding

- What is the structure of an S-layer, and what are its functions?
- What are some alternate arrangements of cell envelope structure?

II • Cell Surface Structures and Inclusions

Many prokaryotic cells contain a cell surface layer that can have a variety of functions. Cytoplasmic inclusions may also be present and function as food reserves or bestow upon the cell a unique capacity of ecological value.

The cell envelope governs many aspects of how microbes interact with their environments and with other cells. Likewise, many other structures visible to microscopy can have profound impacts on cellular function. In particular, structures found on the cell surface and inclusions—structures present within the cell's cytoplasm—have many important functions that govern microbial interactions with the world around them.

2.6 Cell Surface Structures

Many *Bacteria* and *Archaea* secrete sticky or slimy materials on their cell surface that consist of either polysaccharide or protein. However, these are distinct from and external to the cell envelope. The terms “capsule” and “slime layer” are used to describe these layers. These outer layers can mediate attachment, they can protect the cell from attack and from environmental stresses, and they can alter the diffusive environment of the cell.

Capsules and Slime Layers

The terms *capsule* and *slime layer* are used to describe a sticky coat of polysaccharide formed outside of the cell envelope. If the polysaccharide layer is organized in a tight matrix that excludes small particles and is tightly attached to the cell, it is called a **capsule**. Capsules are readily visible by light microscopy if cells are treated with India ink, which contains particulates that stain the background but cannot penetrate the capsule; capsules can also be seen in the electron microscope (Figure 2.16*b–d*). By contrast, if the surface

Figure 2.16 Bacterial capsules and slime formation. (a) A semisolid colony of the bacterium *Leuconostoc mesenteroides* (lifted up by an inoculating loop) contains a thick dextran (glucose polymer) slime layer formed by the cells. (b) Capsules of *Acinetobacter* species observed by phase-contrast microscopy after negative staining with India ink. India ink does not penetrate the capsule and so the capsule appears as a light area surrounding the cell, which appears black. (c) Transmission electron micrograph of a thin section of cells of *Rhodobacter capsulatus* with capsules (arrows) clearly evident; cells are about 0.9 μm wide. (d) Transmission electron micrograph of *Rhizobium leguminosarum* biovar *trifolii* stained with ruthenium red to reveal the capsule. The cell is about 0.7 μm wide.

layer is easily deformed and loosely attached, it will not exclude particles and is more difficult to see microscopically. Such a loosely attached polysaccharide coat is called a *slime layer*, and it is easily detected in colonies of slime-forming species such as the lactic acid bacterium *Leuconostoc* (Figure 2.16a).

Outer surface layers have several functions. Surface polysaccharides assist in the attachment of microorganisms to solid surfaces. As we will see later, pathogenic microorganisms that enter the body by specific routes usually do so by first binding to specific surface components of host tissues; this binding is often facilitated by bacterial cell surface polysaccharides. When the opportunity arises, many bacteria will bind to solid surfaces, often forming a thick layer of cells called a *biofilm* (► Section 4.9). Extracellular polysaccharides play a key role in the development and maintenance of biofilms as well.

Besides attachment, outer surface layers have other functions. These include contributing to the infectivity of a bacterial pathogen and preventing dehydration. For example, the causative agents of the diseases anthrax and bacterial pneumonia—*Bacillus anthracis* and *Streptococcus pneumoniae*, respectively—each contain a thick capsule of either protein (*B. anthracis*) or polysaccharide (*S. pneumoniae*). Encapsulated cells of these bacteria avoid destruction by the host's immune system because the immune cells that would otherwise recognize these pathogens as foreign and destroy them are blocked from doing so by the bacterial capsule. In addition to this role in disease, bacterial outer surface layers bind water, and this helps protect the cell from desiccation in periods of dryness.

Fimbriae, Pili, and Hami

Pili are thin (2–10 nm in diameter) filamentous structures made of protein that extend from the surface of a cell and can have many functions. Short pili that mediate attachment are often called *fimbriae* (Figure 2.17). Pili enable bacterial cells to stick to surfaces, including animal tissues, or to form pellicles (thin sheets of cells on a liquid surface) or biofilms on solid surfaces. All gram-negative bacteria produce pili of one sort or another, and many gram-positive bacteria also contain these structures. Pili, by allowing

Charles C. Brinton, Jr. and Judith Carnathan

Figure 2.18 Pili. The pilus on an *Escherichia coli* cell that is undergoing conjugation. The cells are about 0.8 μm wide. The visibility of the pilus in this electron micrograph has been improved because it is coated with viral particles that bind to the pilin protein.

bacteria to attach to other cells, often contribute to the virulence of pathogens.

Many classes of pili are known, and they can have diverse functions. As already mentioned, pili can enable bacteria to adhere to surfaces and this function can allow pathogens to target and invade specific host tissues. However, pili are diverse and they can have several other important functions as well. For example, *conjugative pili* facilitate genetic exchange by causing cell-to-cell attachment (Figure 2.18) during a process called *conjugation* (► Section 9.8). In addition, *electrically conductive pili* (also known as *nanowires*, ► Section 23.3) can conduct electrons toward or away from the cell and in so doing play an important role in the energy metabolism of diverse microbes (► Sections 14.13 and 15.13). Lastly, a type of pili called *type IV pili* not only facilitate adhesion but also support an unusual form of cell movement called *twitching motility* in certain bacterial species (see Section 2.10).

Twitching motility allows cells to move along a solid surface. In twitching motility, pili are extended away from the cell, attach to a surface, and are subsequently retracted, dragging the cell forward. ATP supplies the energy necessary for extension and retraction of the pilus. On rod-shaped cells that move by twitching, type IV pili are present only at the cell poles. Type IV pili assist in infectivity by certain pathogens, including the gram-negative bacteria *Vibrio cholerae* (cholera) and *Neisseria gonorrhoeae* (gonorrhea) and the gram-positive bacterium *Streptococcus pyogenes* (strep throat and scarlet fever). The twitching motility of these organisms assists them in locating specific sites for attachment to initiate the disease process. Type IV pili are also widespread in the *Archaea*, functioning in surface adhesion and cell aggregation events that lead to biofilm formation.

An unusual group of *Archaea*, the SM1 group, forms a unique attachment structure called a *hamus* (plural, hami) that resembles a tiny grappling hook (Figure 2.19a, b). The SM1 group inhabits anoxic groundwater in Earth's deep subsurface, and hami function to affix cells to a surface to form a networked biofilm (Figure 2.19c). Hami structurally resemble type IV pili except for their barbed terminus, which functions to attach cells both to surfaces and to each other (Figure 2.19c). The biofilms formed by SM1 *Archaea* are likely an ecological strategy that allows these microbes to more efficiently trap the scarce nutrients present in their deep subsurface habitat.

Figure 2.19 Unique attachment structures in the SM1 group of *Archaea*: Hami.

(a) Cells of SM1 *Archaea* showing the pili-like surface structures called hami. (b) Transmission electron micrograph of isolated hami. A hamus “grappling hook” (labeled “Hook” in the micrograph) is about 60 nm in diameter. (c) A biofilm of SM1 cells showing the network of hami connecting individual cells.

Although cells of the SM1 group are not as small as the groundwater ultramicrobacterial cells described in Chapter 1 (see Explore the Microbial World, “Tiny Cells”), they are less than 1 μm in diameter and live in a similar nutrient-limiting habitat. Thus, their hami likely play an important role in preventing cells from being washed away in groundwater flowage.

In addition to the cell surface, the *cytoplasm* of a prokaryotic cell may contain enclosed and sometimes rigid structures that benefit the cell in one way or another, and we consider these now.

- How do fimbriae differ from pili, both structurally and functionally?
- How would inactivating the conjugative pili mechanism in bacteria help prevent antibiotic resistance genes from spreading between bacteria?

2.7 Cell Inclusions

Prokaryotic cells often contain inclusions of one sort or another. Many inclusions store energy or nutrients (such as carbon or phosphorus), but some have other highly specialized functions that confer unique properties on the cells that contain them. Inclusions are often visible in cells with the light microscope and are enclosed by a single-layer (as opposed to a unit) membrane composed of proteins that partitions off the inclusion in the cytoplasm. Storing carbon or other substances in an insoluble form within the cytoplasm reduces osmotic stress and takes up less space compared with storing these substances in a soluble form.

Carbon Storage Polymers

One of the most common inclusion bodies in prokaryotic organisms is **poly- β -hydroxybutyric acid (PHB)**, a lipid that is formed from β -hydroxybutyric acid units. The monomers of PHB polymerize by ester linkage and then the polymer aggregates into granules; the granules can be seen by either light or electron microscopy (**Figure 2.20**). The monomer in the polymer is usually

Figure 2.20 Poly- β -hydroxyalkanoates (PHAs). (a) Chemistry of poly- β -hydroxybutyrate, a common PHA. A monomeric unit is highlighted in color. Other PHAs are made by substituting longer-chain hydrocarbons for the $-\text{CH}_3$ group on the β -carbon. (b) Electron micrograph of a thin section of cells of a bacterium containing granules of PHB. Color photo: Nile red-stained cells of a PHA-containing bacterium.

hydroxybutyrate (C_4) but can vary in length from as short as C_3 to as long as C_{18} . Thus, the more generic term *poly- β -hydroxyalkanoate* (PHA) is often used to describe this class of carbon- and energy-storage polymers. PHAs are synthesized by cells when there is an excess of carbon and are broken down as carbon or energy sources when conditions warrant.

Another carbon storage inclusion is *glycogen*, which is a polymer of glucose; like PHA, glycogen is a reservoir of both carbon and energy and is produced when carbon is in excess. Glycogen resembles starch, the major storage reserve of plants, but differs slightly from starch in the manner in which the glucose units are linked together.

Polyphosphate, Sulfur, and Carbonate Minerals

Many prokaryotic and eukaryotic microbes accumulate inorganic phosphate (PO_4^{3-}) in the form of *polyphosphate* granules (**Figure 2.21a**). These granules are formed when phosphate is in excess and can be drawn upon as a source of phosphate for nucleic acid and phospholipid biosynthesis when phosphate is limiting. In

Figure 2.21 Polyphosphate and sulfur storage products. (a) Phase-contrast photomicrograph of cells of *Helio bacterium modesticaldum* showing polyphosphate as dark granules; a cell is about 1 μm wide. (b) Bright-field photomicrograph of cells of the purple sulfur bacterium *Isochromatium buderi*. The periplasmic inclusions are sulfur globules formed from the oxidation of hydrogen sulfide (H_2S). A cell is about 4 μm wide.

addition, in some organisms, polyphosphate can be broken down to synthesize the energy-rich compound ATP from ADP.

Many gram-negative *Bacteria* and several *Archaea* oxidize reduced sulfur compounds, such as hydrogen sulfide (H_2S); these organisms are the “sulfur bacteria,” discovered by the great Russian microbiologist Sergei Winogradsky (◀ Section 1.13). The oxidation of sulfide generates electrons for use in energy metabolism (chemolithotrophy) or CO_2 fixation (autotrophy). In either case, *elemental sulfur* (S^0) from the oxidation of sulfide may accumulate in the cell in microscopically visible granules (Figure 2.21b). This sulfur remains as long as the source of reduced sulfur from which it was derived is still present. However, as the reduced sulfur source becomes limiting, the S^0 in the granules is oxidized to sulfate (SO_4^{2-}), and the granules slowly disappear. Interestingly, although sulfur globules appear to reside in the cytoplasm (Figure 2.21b), they are actually present in the periplasm (Section 2.4). In these cells the periplasm expands outward to accommodate the growing globules as H_2S is oxidized to S^0 and then contracts inward as S^0 is oxidized to SO_4^{2-} .

Filamentous cyanobacteria have long been known to form carbonate minerals on the external surface of their cells. However, some cyanobacteria also form carbonate minerals *inside* the cell, as cell inclusions. For example, the unicellular cyanobacterium *Gloeomargarita* forms intracellular granules of benstonite, a carbonate mineral that contains barium, strontium, and magnesium (Figure 2.22). The microbiological process of forming minerals is called *biomineralization*. It is unclear why benstonite is formed by *Gloeomargarita*, although it might function as ballast to maintain cells of this cyanobacterium in their habitat, deep in an alkaline lake. Alternatively (or in addition), the mineral could be a way to sequester carbonate (a source of CO_2) to support autotrophic growth.

Figure 2.22 Biomineralization by a cyanobacterium. Electron micrograph of a cell of the cyanobacterium *Gloeomargarita* containing granules of the mineral benstonite $[(\text{Ba},\text{Sr})_6(\text{Ca},\text{Mn})_6\text{Mg}(\text{CO}_3)_{13}]$. A cell is about 2 μm wide.

Gas Vesicles

Some *Bacteria* and *Archaea* can float because they contain **gas vesicles**, structures that confer buoyancy and allow the cells to position themselves in regions of the water column that best suit their metabolisms. The most dramatic examples of gas-vesiculate microbes are those cyanobacteria that form massive accumulations called *blooms* in lakes or other bodies of water. These blooms are commonly on or near the lake surface (Figure 2.23a) where sunlight is most intense and photosynthesis can occur at maximal rates.

Gas vesicles are conical-shaped structures composed of two different proteins; they are hollow yet rigid and of variable length and diameter (Figure 2.23b, c). Gas vesicles in different species vary from 300 to more than 1000 nm in length and from 45 to 120 nm in width. Gas vesicles may number from a few to hundreds per cell and are impermeable to water and solutes but permeable to gases. The composition and pressure of the gas inside a gas vesicle is that in which the organism is suspended. This could be air at 1 atm in cyanobacteria on a lake surface (Figure 2.23a), or a mixture of gases such as N_2 , CO_2 , and H_2 at greater than 1 atm in gas vesiculate species that inhabit anoxic zones deeper in the lake. The presence of gas vesicles in cells can be detected either by light microscopy, where clusters of vesicles, called *gas vacuoles*, appear as irregular bright inclusions (Figure 2.23b), or by transmission electron microscopy of cell thin sections (Figure 2.23c).

Magnetosomes

Some bacteria can orient themselves within a magnetic field because they contain **magnetosomes**. These structures are biomineralized particles of the magnetic iron oxides magnetite $[\text{Fe}(\text{II})\text{Fe}(\text{III})_2\text{O}_4]$ or greigite $[\text{Fe}(\text{II})\text{Fe}(\text{III})_2\text{S}_4]$ (Figure 2.24). Magnetosomes impart a magnetic dipole on a cell, allowing it to orient itself in a magnetic field. This allows the cell to undergo *magnetotaxis*, the process of migrating along Earth’s magnetic field lines (see Section 2.12).

Magnetosome synthesis begins with insertion of magnetosome-specific proteins into the cytoplasmic membrane followed by invagination of the membrane to form a vesicle. The vesicle is then filled with iron—primarily iron in the $\text{Fe}(\text{II})$ oxidation state—and biomineralization proceeds through the activities of the magnetosome

Figure 2.23 Buoyant cyanobacteria and their gas vesicles. (a) Flotation of a bloom of gas-vesiculate cyanobacteria in a freshwater lake. (b) Phase-contrast photomicrograph of *Anabaena*. Clusters of gas vesicles form phase-bright gas vacuoles (small arrows). (c) Transmission electron micrograph of a dividing cell of *Microcystis*. proteins, which includes an iron oxidase enzyme that catalyzes formation of the Fe(III) needed to form the magnetic minerals. The morphology of magnetosomes varies and appears to be species-specific; several morphologies are possible, but square, rectangular, or spike-shaped magnetosomes are most common.

We now consider a special case of a cytoplasmic enclosed cell structure—the endospore.

Check Your Understanding

(c) Transmission electron micrograph of magnetosomes from an unnamed magnetic coccus. The arrow points to the membrane that surrounds each magnetosome. A single magnetosome is about 90 nm wide.

2.8 Endospores

Many microbes produce spore structures that allow them to survive unfavorable conditions. However, certain species of *Bacteria* produce specialized spores called **endospores** (Figure 2.25). Endospores (the prefix *endo-* means “within”) are highly differentiated dormant cells that function as survival structures and can tolerate harsh

Figure 2.25 The bacterial endospore. Phase-contrast photomicrographs showing different intracellular locations of endospores in different species of bacteria. Endospores appear bright by phase-contrast microscopy.

environmental conditions, including extreme heat, radiation, chemical exposure, drying, and nutrient depletion. Endospores are not reproductive structures, such as the spores of fungi, but are rather the dormant stage of a bacterial life cycle: vegetative cell → endospore → vegetative cell (Figure 2.26).

Many microbes can form spores or spore-like structures, including the myxospores of myxobacteria (► Section 15.16), the arthrospores of actinomycetes (► Section 16.12), and various forms of cysts, but endospores are exceptional for their extreme resistance to environmental challenges. Most notably, endospores are the only type of spore that can tolerate high heat, being able to survive for hours in boiling water. And, because of their unique structure, endospores can remain dormant for hundreds and perhaps even thousands of years, only to germinate and grow when conditions become favorable. Endospores are easily dispersed by wind, water, or through the animal gut, and hence endospore-forming bacteria are widely distributed in nature.

Endospores are only produced by two groups of bacteria, the *Bacillales* and *Clostridiales*, both of which are gram-positive bacteria of the phylum *Firmicutes*. These bacteria share an ancestor and so it is likely that the ability to form endospores evolved only once, though many species within these groups have lost the ability to form endospores over time. The best-studied endospore formers are in the genera *Bacillus* and *Clostridium*. These bacteria are found widely in soil and other environments, and some are well-known pathogens of humans and other animals. In particular, endospore-forming bacteria are a major cause of food spoilage and foodborne disease. Botulism, tetanus, and several foodborne bacterial infections are caused by species of endospore-forming bacteria (Chapters 32 and 33).

Endospore Formation and Germination

The process of cellular differentiation that results in endospore formation is called *sporulation*. During endospore formation, a vegetative cell is converted through a process of cellular differentiation

Figure 2.26 The life cycle of an endospore-forming bacterium. The phase-contrast photomicrographs are of cells of *Clostridium pascui*. A vegetative cell is about 0.8 μm wide.

Figure 2.27 Endospore germination in *Bacillus*. Conversion of an endospore into a vegetative cell. This series of phase-contrast photomicrographs shows the sequence of events starting from (a) a highly refractile free endospore. (b) *Activation*: The spore becomes less refractile as the spore is hydrated. (c) *Germination*: the spore begins to develop into a vegetative cell. (d) *Outgrowth*: the vegetative cell emerges and begins to divide.

into a nongrowing, heat-resistant, and light-refractive structure (Figure 2.26). Sporulation is typically triggered when some nutrient becomes limiting. When the cell senses this, the developmental process that converts a vegetative cell into an endospore begins and is controlled by a complex regulatory system we will consider later (► Section 8.6). Our focus here is not on regulation but instead on the major steps in the process.

An endospore can remain dormant for years, but when conditions are favorable for growth, it can convert back to a vegetative cell rapidly through the process of *germination* (Figure 2.26). Germination is usually triggered by the availability of nutrients, such as certain amino acids or sugars. This process occurs in three steps: *activation*, *germination*, and *outgrowth* (Figure 2.27). The overall process occurs over a period of just a few minutes, and it is characterized by hydration of the spore, which results in loss of its heat and chemical resistance, the loss of specific spore structures and the regeneration of vegetative cell structures, and ultimately, the onset of vegetative growth by binary fission.

Endospore Structure and Features

Endospores differ in many ways from vegetative cells (Table 2.1). Endospores are visible by light microscopy as strongly refractile structures (Figures 2.25 and 2.26). Endospores are impermeable to most dyes, so occasionally they are seen as unstained regions within cells that have been stained with basic dyes such as methylene blue. To stain endospores, special stains and procedures must be used. In the classical endospore-staining protocol, the stain malachite green is used and is infused into the spore with steam.

The structure of the endospore as seen with the electron microscope differs distinctly from that of the vegetative cell (Figure 2.28). The endospore contains many layers absent from the vegetative cell. The innermost region of the endospore is called the *core*; this contains DNA and ribosomes and develops from the cytoplasm of the vegetative cell. Surrounding the core is the *inner membrane*, the *cortex*, and the *outer membrane* (Figure 2.28). The inner membrane develops from the cytoplasmic membrane of the vegetative cell, the cortex is composed of peptidoglycan, and the outer membrane is a special membrane formed during sporulation (and should not be confused with the LPS-containing outer membrane of

TABLE 2.1 Differences between endospores and vegetative cells

Characteristic	Vegetative cell	Endospore
Microscopic appearance	Nonrefractile	Refractile
Calcium content	Low	High
Dipicolinic acid	Absent	Present
Enzymatic activity	High	Low
Respiration rate	High	Low or absent
Macromolecular synthesis	Present	Absent
Heat resistance	Low	High
Radiation resistance	Low	High
Resistance to chemicals	Low	High
Lysozyme	Sensitive	Resistant
Water content	High, 80–90%	Low, 10–25% in core
Small acid-soluble spore proteins	Absent	Present

gram-negative cells). Beyond the outer membrane is the *endospore coat* (Figure 2.28), composed of layers of spore-specific proteins, and some (but not all) endospores also have an outer proteinaceous layer called the *exosporium* (Figure 2.28).

The secret to the endospore toughness, and the reasons that endospores are so highly refractile, lies in the dehydration of the core. The endospore core contains less than one-quarter of the water found in the vegetative cell (Table 2.1). Dehydration greatly increases heat

and chemical resistance and causes enzymes in the core to become inactive (but not denatured). Dehydration of the core is facilitated by the accumulation of a substance called **dipicolinic acid**, a distinctive characteristic of endospores. Endospores also contain large amounts of calcium (Ca^{2+}), most of which is complexed with dipicolinic acid. The calcium–dipicolinic acid complex forms about 10% of the dry weight of the endospore and functions to bind water, helping to dehydrate the developing endospore. In addition, the complex inserts between bases in DNA, which helps stabilize DNA against heat denaturation.

The endospore core also contains high levels of *small acid-soluble spore proteins* (SASPs). These proteins are only made during the sporulation process and have at least two functions. SASPs bind tightly to DNA in the core and protect it from potential damage from ultraviolet radiation, desiccation, and dry heat. Ultraviolet resistance is conferred when SASPs alter the physical structure of DNA, causing it to become more compact. This change in DNA structure causes it to be more resistant to mutations and other forms of potential damage caused by harsh chemicals or UV radiation (► Section 12.4) and also increases its resistance to thermal denaturation. In addition, SASPs function as a carbon and energy source for the outgrowth of a new vegetative cell from the endospore during germination.

The Sporulation Cycle

Sporulation is a form of cellular differentiation (◀ Figure 1.5), and many genetically directed events occur during the conversion from vegetative growth to sporulation. The structural changes in sporulating cells of *Bacillus* are shown in Figure 2.29. In *Bacillus subtilis*, which has been studied in detail, the conversion of a vegetative cell into an endospore takes about 8 hours and begins with asymmetric cell division and the formation of a *forespore* (Figure 2.29). Engulfment of the forespore by the mother cell results in the formation of the outer membrane that surrounds the developing endospore; the outer membrane forms from part of the mother cell's cytoplasmic membrane. Key events in endospore formation such as asymmetric cell division, cortex formation, and SASP production take place in a defined sequence and at specific times in the sporulation cycle (Figure 2.29). Genetic studies of mutants of *Bacillus subtilis*, each blocked at one of the stages of sporulation, indicate that more than 200 sporulation-specific genes exist. These genes are turned on and off in a genetic program that governs cellular differentiation, a process we will consider in detail when we examine the genetic regulation of sporulation (► Section 8.6).

Prokaryotic cells are not static entities, and so we now turn our attention to how and why cell movements occur.

Figure 2.28 Structure of the bacterial endospore. (a) Transmission electron micrograph of a thin section through an endospore of *Bacillus megaterium*. Note that the composition of the endospore “outer membrane” is not the same as the outer membrane (LPS layer) of gram-negative bacteria shown in Figure 2.12. (b) Fluorescent photomicrograph of a cell of *Bacillus subtilis* undergoing sporulation. The green color is a fluorescent dye that specifically stains a sporulation protein in the endospore coat.

Check Your Understanding

- What features differentiate an endospore from a vegetative cell?
- Ingestion of honey by infants can cause botulism as it often contains *Clostridium botulinum* endospores. Why wouldn't heating honey prevent this from occurring?
- How is the outer membrane of an endospore formed, and how does this structure differ from the outer membrane in the gram-negative cell envelope?

Figure 2.29 Major events in endospore formation. The steps depicted are those defined from genetic and microscopic analyses of sporulation in *Bacillus subtilis*, the model organism for studies of sporulation. SASPs, small acid-soluble proteins.

III • Cell Locomotion

Prokaryotic cells move about their environments by powering motility devices that allow them to swim or crawl, and they can move in specific directions in response to chemical or physical signals.

We finish our survey of prokaryotic cell structure and function by examining cell locomotion. Many microbial cells can move under their own power. Motility allows cells to reach different parts of their environment, and in nature, a new location may offer a cell additional resources or protection from harmful substances and ultimately spell the difference between life and death.

We examine here the two major types of prokaryotic cell movement, *swimming* and *gliding*. We then consider how motile cells are able to move in a directed fashion toward or away from particular stimuli (a phenomenon called *taxis*) and present examples of these simple behavioral responses.

2.9 Flagella, Archaeella, and Swimming Motility

Many *Bacteria* are motile by swimming due to a structure called the **flagellum** (plural, flagella) (Figure 2.30); an analogous structure called the **archaellum** is present in many *Archaea*. Flagella and archaella are tiny rotating machines that function to push or pull the cell through a liquid.

Flagella and Flagellation

Bacterial flagella are long, thin appendages (15–20 nm wide, depending on the species) free at one end and anchored into the cell at the other end. Flagella can be stained and observed by light microscopy (Figure 2.30) or electron microscopy (Figure 2.31).

Flagella can be anchored to a cell in different locations. In **polar flagellation**, the flagella are attached at one or both ends of a cell (Figure 2.30b). Occasionally, a group of many flagella (called a *tuft*) may arise at one end of the cell, a type of polar flagellation called *lophotrichous* (Figure 2.30c). Tufts of flagella can sometimes be seen in large unstained cells by dark-field or phase-contrast microscopy (Figure 2.32). When a tuft of flagella emerges from both poles of the cell, flagellation is called *amphitrichous*. In contrast to these more

Figure 2.30 Bacterial flagella. Classic light photomicrographs taken by Einar Leifson of bacteria containing different arrangements of flagella. Cells are stained with the Leifson flagella stain. (a) Peritrichous. (b) Polar. (c) Lophotrichous.

Figure 2.31 Bacterial flagella as observed by negative staining in the transmission electron microscope. (a) A single polar flagellum. (b) Peritrichous flagella. Both micrographs are of cells of the phototrophic bacterium *Rhodocista centenaria*, which are about $1.5\ \mu\text{m}$ wide. Cells of *R. centenaria* are normally polarly flagellated but under certain growth conditions form peritrichous flagella. See Figure 2.41b for a photo of colonies of *R. centenaria* cells that move toward an increasing gradient of light (phototaxis).

specific sites of flagellation, in **peritrichous flagellation** (Figures 2.30a and 2.31b), flagella are inserted around the cell surface.

Flagella do not rotate at a constant speed but increase or decrease their rotational speed in relation to the strength of the proton motive force. Flagella can rotate at up to 1000 revolutions per second to support a swimming speed of up to 60 cell-lengths/sec. The fastest

Figure 2.32 Bacterial flagellar tufts observed in living cells. (a) Dark-field photomicrograph of a group of large rod-shaped bacteria with flagellar tufts at each pole (a condition called *amphitrichous flagellation*). A single cell is about $2\ \mu\text{m}$ wide. (b) Phase-contrast photomicrograph of cells of the large phototrophic purple bacterium *Rhodospirillum rubrum* that contain a tuft of lophotrichous flagella emerging from one of the poles. A cell measures about $4 \times 25\ \mu\text{m}$.

known land animal, the cheetah, can move at about 25 body-lengths/sec. Thus, a bacterium swimming at 60 cell-lengths/sec is actually moving over twice as fast—relative to its size—as the fastest animal!

The swimming motions of polarly and lophotrichously flagellated organisms differ from those of peritrichously flagellated organisms, and these can be distinguished microscopically (Figure 2.33). Peritrichously flagellated organisms typically move slowly in a straight line, stop and then head off in a new direction. By contrast, polarly flagellated organisms often move more rapidly and continuously, and some are able to reverse their direction. The different behavior of flagella on polar and peritrichous organisms, including differences in reversibility of the flagellum, is illustrated in Figure 2.33.

Figure 2.33 Movement in peritrichously and polarly flagellated prokaryotic cells. (a) Peritrichous: Forward motion is imparted by all flagella forming into a bundle and rotating counterclockwise (CCW). Clockwise (CW) rotation causes the bundle to break apart and the cell to tumble. A return to counterclockwise rotation leads the cell off in a new direction. (b) Polar: Cells change direction by reversing flagellar rotation (thus pulling instead of pushing the cell) or, with unidirectional flagella, by stopping periodically to reorient and then moving forward by clockwise rotation of its flagella. The gray arrow above each cell shows the direction the cell is traveling.

Flagella Structure and Activity

Bacterial flagella are rigid and helical (unlike eukaryal flagella, which are whiplike). The main part of the flagellum, called the *filament*, is composed of many copies of a protein called *flagellin*. The amino acid sequence of flagellin is highly conserved in *Bacteria*, suggesting that flagellar motility evolved early and has deep roots within this domain. In addition to the filament, a flagellum consists of several other components. A wider region at the base of the filament called the *hook* consists of a single type of protein and connects the filament to the flagellum motor in the *basal body* (Figure 2.34).

Flagella:
Structure

Figure 2.34 Structure and function of the flagellum in gram-negative *Bacteria*.

The L ring is embedded in the LPS and the P ring in peptidoglycan. The MS ring is embedded in the cytoplasmic membrane and the C ring is found within the cytoplasm. The stator (Mot proteins) is embedded both within the cytoplasmic membrane and the peptidoglycan. Proton translocation through channels within the stator cause the MS ring to rotate, thereby driving rotation of the attached rod and flagellum. Flagellin molecules move from the export apparatus through a narrow channel in the rod and filament to reach the site of flagellar synthesis at the filament tip. The Mot proteins function as the flagellar motor. The flagellar motor rotates the filament to propel the cell through the medium. Inset photos: Top left, a cell of the purple sulfur bacterium *Chromatium* containing a tuft of polar flagella; Top right, transmission electron micrograph of a flagellar basal body from a cell of *Salmonella enterica* with the various rings labeled.

The flagellum motor is a reversible rotating machine composed of more than 25 proteins and anchored in the cytoplasmic membrane and cell wall. The motor consists of a central rod that passes through a series of rings. In gram-negative bacteria, an outer ring, called the *L ring*, is anchored in the outer membrane (Section 2.4). A second ring, called the *P ring*, is anchored in the peptidoglycan layer (Section 2.3). A third set of rings, called the *MS* and *C rings*, are located within the cytoplasmic membrane (Section 2.1) and the cytoplasm, respectively (Figure 2.34). In gram-positive bacteria, which lack an outer membrane, only the inner pair of rings is present. Surrounding the inner rings and anchored in the cytoplasmic membrane and the peptidoglycan is the *stator*, which is composed of *Mot* proteins. On the cytoplasmic side of the MS ring is the *export apparatus*, a type III secretion system (► Section 6.13) that facilitates synthesis of the flagellum.

The flagellum motor contains two main components: the *rotor* and the *stator*. The rotor consists of the central rod and the L, P, C, and MS rings. The stator is comprised of Mot proteins, which surround the rotor and function to generate torque. Collectively, these structures make up the flagellar **basal body** (Figure 2.34). Rotation of the flagellum occurs at the expense of the proton motive force (Section 2.1), and it is thought that rotation is caused by a type of “proton turbine” process. In this model, proton translocation through channels within the stator complex cause the MS ring to rotate, thereby driving rotation of the attached rod and flagellum. The L and P rings act like bushings within which the rod rotates. Protons flowing through the Mot proteins exert electrostatic forces on helically arranged charged residues on rotor proteins and cause the MS ring to rotate. About 1200 protons are translocated by each rotation of the flagellum. The rotational speed of the flagellum is set by the proton flow rate through the Mot proteins, which is a function of the intensity of the proton motive force. The flagellar motors of different microbes are able to generate different amounts of torque, causing significant differences in swimming speed; such adaptations are driven by adding or subtracting subunits from the stator and C ring, which presumably changes the “gear ratio” of the motor.

Flagellar Synthesis

Several genes encode the motility apparatus of *Bacteria*. In *Escherichia* and *Salmonella* species, in which motility studies have been extensive, over 50 genes are linked to motility in one way or another. These genes encode the structural proteins of the flagellum and motor apparatus, of course, but also encode proteins that export the structural proteins through the cytoplasmic membrane to the outside of the cell and proteins that regulate the synthesis of new flagella.

A flagellar filament grows not from its base, as does an animal hair, but from its tip. The MS ring is synthesized first and inserted into the cytoplasmic membrane. Then other anchoring proteins are synthesized along with the hook and the cap before the filament forms (Figure 2.35). Flagellin molecules synthesized in the cytoplasm are exported through the *export apparatus* (Figure 2.34) present on the cytoplasmic side of the basal body. The export apparatus shuttles flagellin molecules into a 3-nm channel that runs through the center of the basal body and the hollow flagellar filament. The flagellin

Figure 2.35 Flagella biosynthesis. Synthesis begins with assembly of MS and C rings in the cytoplasmic membrane, followed by the other rings, the hook, and the cap. Flagellin protein flows through the hook to form the filament and is guided into position by cap proteins.

subunits are ultimately passed to the end of the filament where they attach to the terminus of the growing flagellum. Cap proteins assist flagellin molecules to assemble in the proper fashion at the flagellum tip (Figure 2.35). Approximately 20,000 flagellin protein molecules are needed to make one filament. The flagellum grows more or less continuously until it reaches its final length. Broken flagella still rotate and can be repaired with new flagellin units passed through the filament channel to replace the lost ones.

Archaea

As in *Bacteria*, swimming motility is widespread among species of *Archaea* and is driven by the rotation of their flagellum analog, the *archaellum*. However, despite their similar function, archaella proteins are unrelated to those of flagella, and in evolutionary terms are more closely related to type IV pili (Section 2.6). Archaella are somewhat smaller than flagella, measuring about 10–13 nm in width (Figure 2.36), which is only slightly wider than type IV pili. Archaella are not hollow and are assembled from their bases much like type IV pili, whereas flagella are hollow and are assembled at their tips (Figure 2.35). Archaellar rotation, like the extension and retraction of type IV pili, is driven by ATP hydrolysis, whereas the energy for flagellar rotation is derived from the proton motive force. In addition, the archaellar motor is structurally simpler than the flagellar motor (compare Figure 2.36 with Figure 2.34), and only 7–12 genes are required to encode the major proteins that make up the archaellar motor, in contrast to the more than 25 genes that encode components of the flagellar motor.

Studies of swimming *Archaea*, such as *Halobacterium*, show that they swim at speeds only about one-tenth that of *Escherichia coli*, and in general, *Archaea* swim much more slowly than *Bacteria*. This could be due to the smaller diameter of the archaellum compared to the flagellum, which should reduce the torque the structure can generate. It could also be due to differences in the construction of the motor and how it is powered. However, some *Archaea* have found a way to overcome these limitations. For example, cells of *Methanocaldococcus* (Figure 2.36c) swim nearly 50 times faster than

cells of *Halobacterium* and 10 times faster than cells of *Escherichia coli*. In fact, *Methanocaldococcus* swims at nearly 500 cell-lengths per second, which in a relative sense makes it one of the fastest organisms on Earth!

We now compare swimming motility with mechanistically quite different forms of cell movement but ones that still allow the cell to move about and explore its environment.

Check Your Understanding

- Cells of *Salmonella* are peritrichously flagellated, those of *Pseudomonas* polarly flagellated, and those of *Spirillum* lophotrichously flagellated. Using a sketch, show how each organism would appear in a flagella stain.
- Compare flagella and archaella in terms of their structure, function, and energy source.
- The genes for flagellin are highly conserved between bacterial species. What does this imply about the importance of motility during bacterial evolution?

2.10 Surface Motility

Many motile microbes are unable to swim and instead crawl over surfaces in various ways. These forms of surface motility require attachment to a surface and are independent of flagella or archaella. Surface motility results in distinctive colony morphology because cells can move out and away from the center of the colony (Figure 2.37). All forms of surface motility are considerably slower than swimming motility, usually less than 10 $\mu\text{m}/\text{sec}$. Finally, whereas nearly all swimming motility in *Bacteria* and *Archaea* is driven by flagella and archaella (Section 2.9), surface motility can be produced by a diversity of different systems, the most well characterized of which are *twitching motility* and *gliding motility*.

Twitching Motility

Twitching motility requires type IV pili (Section 2.6), which extend from one pole of the cell, attach to a surface, and then retract to pull

(c)

Figure 2.36 Archaeella. (a) Depiction of an archaeellum embedded in an S-layer and cytoplasmic membrane; compare with the bacterial flagellum in Figure 2.34. The archaeellum and its motor differ from flagella in that the archaeellum has a smaller diameter, it is not hollow, its motor has fewer proteins, and the energy for rotation comes from ATP hydrolysis and not from consumption of the proton motive force. (b) Negatively stained transmission electron micrograph of purified archaeella. (c) Scanning electron micrograph of cells of *Methanocaldococcus* containing multiple archaeella.

the cell forward (Figure 2.38a). The energy required to catalyze the activity of type IV pili comes from ATP hydrolysis. Twitching motility has been described in many *Bacteria* and some *Archaea*. For example, species of the gram-negative bacterium *Pseudomonas* are often capable of twitching motility and this trait is important to their ability to form biofilms (► Section 4.9). Twitching motility has also been well described in myxobacteria, which are social predatory bacteria whose cells can work together to consume other bacteria.

(d)

Figure 2.37 Gliding bacteria. (a, b) The large filamentous cyanobacterium *Oscillatoria* has cells about 35 μm wide. (b) *Oscillatoria* filaments gliding on an agar surface. (c) Masses of the bacterium *Flavobacterium johnsoniae* gliding away from the center of the colony (the colony is about 2.7 mm wide). (d) Nongliding mutant strain of *F. johnsoniae* showing typical colony morphology of nongliding bacteria (the colonies are 0.7–1 mm in diameter). See also Figure 2.41.

Myxobacteria exhibit two forms of motility: social motility, which is caused by twitching, and adventurous motility, which is caused by gliding (see below). Twitching motility allows cells to move together in groups, and this trait is facilitated by the production of both type IV pili and the secretion of extracellular polysaccharides that aid in cellular cohesion.

Gliding Motility

Gliding motility (Figure 2.38b) is defined as a smooth motion along the long axis of a cell without the aid of external propulsive

Figure 2.38 Surface motility. (a) Twitching motility employs type IV pili. These structures require ATP hydrolysis to extend (up to several micrometers) and then retract, causing the cell to move forward; movement occurs in discrete increments. (b) Gliding motility requires a helical intracellular protein track that interacts with gliding motors and extracellular adhesion proteins. The proton motive force drives rotation of gliding motors that translate this force to the helical track, causing adhesion proteins to move in a helical pattern; this results in continuous forward motion and clockwise rotation of the cell.

structures (such as pili or attachment organelles). Gliding motility is a continuous form of movement, very unlike swimming motility, in which cells frequently stop and then swim off in a random new direction. Gliding bacteria are typically filamentous or rod-shaped in morphology, and while gliding has been observed among diverse species of *Bacteria*, no gliding *Archaea* are known. The adventurous motility of myxobacteria is a form of gliding that has been well studied, and many species of the *Bacteroidetes* such as *Flavobacterium* also exhibit gliding motility.

Gliding has been best studied in *Myxococcus* and *Flavobacterium* (Figure 2.37c), and the mechanism of gliding in these two organisms is likely to be quite similar. These organisms both possess a helical intracellular track made of proteins that run in a continuous loop around the cell (Figure 2.38b). Associating with this track are “gliding motors,” rotary motors that are driven by the proton motive force, and which are evolutionarily and operationally similar to the flagellar motor (see Figure 2.34). These organisms also have adhesion proteins that grab onto surfaces on the outside of the cell. While the exact mechanism of gliding remains unknown, it is thought that the gliding motor associates with the helical track, and rotation of the motor causes displacement of the track relative to the motor (or of the motor relative to the track). This movement is in some way transduced to the surface adhesion proteins, causing them to move in a helical direction around the surface of the cell. The net result is that the cell is propelled forward over the surface and caused to rotate around its axis as it moves forward (Figure 2.38b).

We now consider how these various forms of prokaryotic cell motility can move cells in specific directions, which allows them to both exploit useful nutrients and avoid harmful substances.

Check Your Understanding

- How does gliding motility differ from swimming motility in both mechanism and requirements?
- Contrast the mechanism of twitching motility with that of gliding motility.

2.11 Chemotaxis

Cells of *Bacteria* and *Archaea* have evolved numerous systems that allow them to sense and respond to chemical and physical stimuli in their environments. For example, microbes are able to sense and move toward a food source. Such a directed movement is called *taxis* (plural, *taxes*). **Chemotaxis**, a response to chemicals, and **phototaxis**, a response to light, are two well-studied forms of taxis. The ability of a cell to move toward or away from various stimuli has ecological significance in that the directed movement may enhance a cell's access to resources or allow it to avoid harmful substances that could damage or kill it.

Chemotaxis has been well studied in *Bacteria* that use swimming motility; these organisms sense environmental stimuli and transmit signals to the flagellum causing it to alter its rotation. In addition, most *Archaea* that exhibit swimming motility are also chemotactic, and several of the proteins that control chemotaxis in *Bacteria* are similar to those found in *Archaea*. Gliding bacteria are also often chemotactic and can alter their direction in response to environmental stimuli. Phototaxis is often observed in filamentous cyanobacteria (Figure 2.37a, b) which move toward or away from a light source. In Section 7.6 we examine in detail the molecular mechanism of chemotaxis and its genetic regulation in the model bacterium *Escherichia coli*. For now, we will focus on the general principles by which chemotaxis operates.

Chemotaxis in Peritrichously Flagellated *Bacteria*

Much research on chemotaxis has been done with the peritrichously flagellated bacterium *E. coli*. In the absence of an attractant, cells move in a random fashion that includes *runs*, in which the cell is swimming forward in a smooth fashion, and *tumbles*, when the cell stops and jiggles about randomly (Figure 2.39). During a run, the flagellar motor rotates *counterclockwise*, causing the flagella to coil together into a bundle that propels the cell forward. By contrast, when flagella rotate *clockwise*, the bundle of flagella pushes apart, forward motion ceases, and the cells tumble randomly (Figure 2.39a). Following a tumble, the cell will begin a new run in a random direction. Thus, in the absence of an

(a) No attractant present: Random movement (b) Attractant present: Directed movement

Figure 2.39 Chemotaxis in a peritrichously flagellated bacterium. (a) In the absence of a chemical attractant, the cell swims randomly in runs, changing direction during tumbles. (b) In the presence of an attractant, runs become biased, and the cell moves up the gradient of the attractant. The attractant gradient is depicted in green, with the highest concentration where the color is most intense.

attractant, the cell moves about its environment in random fashion through a series of runs and tumbles.

To understand chemotaxis, consider what happens when *E. coli* encounters a chemical attractant, such as the sugar glucose (Figure 2.39b). Because of diffusion, the concentration of the attractant will increase when the cell is moving toward the attractant. During chemotaxis cells will tend to move toward the attractant over time, but cells do not move continuously nor directly toward the attractant; instead, they exhibit a behavior known as a *biased random walk*. The key to this mechanism is that cells sample the concentration of attractant not over space, but rather *over time*. As the cell is swimming in a random direction, it continues to sense the concentration of attractant over time. If the concentration goes up, runs become longer and tumbles less frequent, but if the concentration goes down, runs become shorter and tumbles more frequent. The biased random walk causes net movement toward the attractant (Figure 2.39b), and this mechanism is remarkably effective for bringing cells to the source of an attractant. For a repellent, the same mechanism applies, but the response is reversed, with longer runs triggered by a *decrease* in concentration of the repellent. Attractants and repellents are sensed by a series of membrane proteins called *chemoreceptors*. Chemoreceptors sense the concentration of particular chemicals and transduce this information to flagella, causing them to alter their rotation (► Section 7.6).

Chemotaxis in Polarly Flagellated Bacteria

Chemotaxis in polarly flagellated cells is similar but not identical to chemotaxis in peritrichously flagellated cells such as *E. coli*. Many polarly flagellated bacteria, such as *Pseudomonas* species, which have a single polar flagellum rather than a tuft, do not tumble when they reverse their flagellum. Instead, they swim backwards when their flagellum reverses its direction of rotation (Figure 2.33b). In contrast, the phototrophic bacterium *Rhodobacter* has a single polar flagellum

that is not reversible; it can only start and stop its rotation. Both of these polarly flagellated bacteria rely on Brownian motion when stopped to randomly reorient the cell (Figure 2.33b). Then as the flagellum begins to rotate again, the cell moves off in a new direction. Despite this seemingly random activity, cells of *Rhodobacter* are strongly chemotactic to various organic compounds and to oxygen and light. Chemotactic organisms, by employing a *biased* random walk, can navigate effectively through their environments toward conditions that favor growth and away from those that could inhibit growth or otherwise cause harm.

Measuring Chemotaxis

Bacterial chemotaxis can be measured in a chemotaxis assay in which a small glass capillary tube containing an attractant is immersed into a suspension of motile bacteria. A chemical gradient extends from the tip of the capillary into the surrounding medium, with the chemical concentration decreasing with distance from the tip (Figure 2.40). When an

attractant is present, chemotactic bacteria will move toward it, forming a swarm around the open tip (Figure 2.40c) with many of the bacteria swimming into the capillary tube. Of course, because of random movements some chemotactic bacteria will swim into the capillary even if it does not contain an attractant (control solution, Figure 2.40b). However, when an attractant is present, the number of cells within the capillary will increase significantly (Figure 2.40e). If the capillary contains a repellent, the number of bacteria within the capillary will be fewer than in the control (Figure 2.40d). This capillary method can be used to screen chemicals to see if they are attractants or repellents for a given bacterium.

Chemotaxis can also be observed microscopically. It is possible to quantify chemotactic behavior using a video camera that captures the positions of bacterial cells with time and records the motility tracks of each cell (Figure 2.40f). This method has been used to study chemotaxis of microbes in natural environments. In nature, nutrients are often excreted from larger microbial cells whether they are living or dead. Algae, for example, produce both organic compounds and oxygen (O_2 , from photosynthesis), which can trigger chemotactic movements of bacteria toward the algal cell (Figure 2.40f). Chemotaxis can result in complex cellular interactions in nature including competition for resources and cooperation by recycling metabolic products.

Check Your Understanding

- Describe how bacteria use a biased random walk to move toward an attractant.
- Contrast the motility of a peritrichously flagellated bacterium such as *Escherichia coli* with that of a polarly flagellated bacterium such as a species of *Pseudomonas*.
- In a capillary tube assay, why is it necessary to use a control that lacks attractant?

(f) Tracks of motile bacteria in seawater swarming around an algal cell (large white spot, center) photographed with a tracking video camera system attached to a microscope. The bacterial cells are showing positive aerotaxis by moving toward the oxygen-producing algal cell. The alga is about 60 μm in diameter.

2.12 Other Forms of Taxis

Chemotaxis is a directed movement with respect to a chemical gradient, but many other forms of sensory response can govern microbial motility. For example, *osmotaxis* is directed movement with respect to a gradient of ionic strength, *hydrotaxis* is directed movement with respect to a gradient of available water, *aerotaxis* is directed movement with respect to gradients of O_2 , and *phototaxis* is directed movement with respect to a gradient in light intensity. Here we will consider phototaxis and aerotaxis, two taxes that have been particularly well studied.

Phototaxis

Many phototrophic microorganisms can move toward light, a process called *phototaxis*. Phototaxis allows a phototrophic organism to position itself most efficiently to receive light for photosynthesis. For example, if motile phototrophic purple bacteria are placed on a microscope slide that is illuminated with a spectrum of light they will move preferentially toward certain wavelengths (Figure 2.41a). The wavelengths of light at which the bacteria accumulate correspond to the wavelengths of light that are absorbed by their photosynthetic pigments. These pigments include, in particular, bacteriochlorophylls and carotenoids (Chapter 14).

Two different light-mediated taxes are observed in phototrophic bacteria. One, called *scotophobotaxis*, is easily observed in the microscope. Scotophobotaxis occurs when a phototrophic bacterium happens to swim into darkness outside the illuminated field of view of the microscope. Entering darkness negatively affects photosynthesis,

and thus cellular energy levels, and this signals the cell to tumble with greater frequency until it reenters the light by a biased random walk. Scotophobotaxis is a mechanism to prevent phototrophic cells from swimming away from a lighted zone into darkness, and this likely improves their competitive success in nature.

Phototaxis differs from scotophobotaxis in that cells move with respect to a *gradient* of light intensity, whereas scotophobotaxis is a response only to the absence of light. Phototaxis is analogous to chemotaxis except that the attractant is light instead of a chemical. In some phototactic organisms, such as the highly motile phototrophic purple bacterium *Rhodospira rubra* (Figure 2.31), entire colonies of cells show phototaxis and move in unison toward the light (Figure 2.41b).

Several components of the regulatory system that control chemotaxis also control phototaxis. A *photoreceptor*, a protein that functions similarly to a chemoreceptor but which senses a gradient of light instead of chemicals, is the initial sensor in the phototaxis response. The photoreceptor then interacts with the same cytoplasmic proteins that control flagellar rotation in chemotaxis, maintaining the cell in a run if it is swimming toward an increasing intensity of light. Section 7.6 describes the activities of these proteins in more detail.

Aerotaxis and Magnetotaxis

Aerotaxis is directed motility with respect to O_2 (see Figure 2.40f). Aerobic organisms require O_2 and may exhibit a positive aerotactic response, swimming toward increasing concentrations of O_2 . We will see in the next chapter, however, that O_2 is toxic to many

(a)

(b)

Figure 2.41 Phototaxis of phototrophic bacteria. (a) Scotophobic accumulation of the phototrophic purple bacterium *Thiospirillum jenense* at wavelengths of light at which its pigments absorb. A light spectrum was displayed on a microscope slide containing a dense suspension of the bacteria; after a period of time, the bacteria had accumulated selectively and the photomicrograph was taken. The wavelengths at which the bacteria accumulated are those at which the photosynthetic pigment bacteriochlorophyll *a* absorbs. (b) Phototaxis of an entire colony of the purple phototrophic bacterium *Rhodocista centenaria*. These strongly phototactic cells move in unison toward the light source at the top. See Figure 2.31 for electron micrographs of flagellated *R. centenaria* cells.

microbes. *Microaerophiles* are aerobic organisms that require O_2 but are killed when the concentration of O_2 is too high. Microaerophiles often use aerotaxis to position themselves at an optimum concentration of O_2 (usually between 1% and 5% O_2). Microaerophily can be a challenging lifestyle because either too much or too little O_2 can mean death, and O_2 gradients are highly dynamic because many organisms either produce or consume O_2 . Hence, some microaerophiles have evolved aerotactic mechanisms that help them better navigate dynamic gradients of O_2 . Indeed, a movement of only a few tens of micrometers may be necessary to place aerotactic cells in a more suitable gaseous environment.

Magnetosomes (Section 2.7) are found in specialized microaerophiles, referred to as *magnetotactic bacteria*, which are found in sediments, lakes, and ponds where concentrations of O_2 are naturally low. Because Earth is a sphere, its magnetic field lines have a significant vertical component where they intersect the surface. Magnetosomes allow magnetotactic bacteria to align themselves with these

magnetic field lines. This causes the bacterial cells to point up or down so that they can swim either toward or away from O_2 at the surface. These so-called magnetotactic bacteria do not actually exhibit directed motility toward magnetic fields but instead are exhibiting aerotaxis; their magnetosomes allow them to reduce a three-dimensional biased random walk to a two-dimensional biased random walk and this vastly improves their ability to position themselves in their environment with respect to O_2 .

We now segue from our consideration of the structure and function of major components of prokaryotic cells to examine structure–function issues in eukaryotic cells, many of which are microbial and coexist with prokaryotic cells in the microbial world.

Check Your Understanding

- How does scotophobotaxis differ from phototaxis?
- Explain how magnetosomes contribute to the motility of magnetotactic bacteria.

IV • Eukaryotic Microbial Cells

The cytoplasm of eukaryotic cells contains membrane-bound organelles including the nucleus, mitochondria, and chloroplasts, and several other distinct structures. During cell division, the nucleus divides by mitosis and reproductive structures are formed by the process of meiosis.

Compared with prokaryotic cells, microbial eukaryotes typically have structurally more complex and much larger cells. Microbial eukaryotes include the fungi and a vast diversity of protists as we will see in Chapter 18. Many aspects of eukaryotic cell structure set *Eukarya* apart from *Archaea* and *Bacteria*, but the defining feature of the eukaryotic cell is its nucleus.

2.13 The Nucleus and Cell Division

A double membrane–enclosed nucleus is a universal feature of the eukaryotic cell. Mitochondria are also nearly universal among eukaryotic cells, although a few unusual protists lack mitochondria. Chloroplasts are found only in phototrophic eukaryotic cells, including plants and diverse algae. Other characteristic eukaryotic structures include the Golgi complex, lysosomes, endoplasmic reticula, and microtubules and microfilaments (Figure 2.42). Some microbial eukaryotes have flagella or cilia—structures that confer motility—and a cell wall is present in many eukaryotic cells, such as the fungi and algae.

Eukaryotic cell membranes contain *sterols*. These rather rigid organic molecules, which are a subclass of steroids and absent from all but a few prokaryotic cells, lend structural strength to the eukaryotic cell, something especially important to those eukaryotes that lack a cell wall, such as many protists and animal cells.

The Nucleus

The **nucleus** contains the chromosomes of the eukaryotic cell. DNA within the nucleus is wound around basic (positively charged)

Figure 2.42 Cutaway schematic of a cell of a microbial eukaryote. Although all eukaryotic cells contain a nucleus, not all organelles and other structures shown are present in all microbial eukaryotes. Not shown is the cell wall, found in fungi, algae, plants, and a few protists.

proteins called **histones**, which tightly pack the negatively charged DNA to form *nucleosomes* (Figure 2.43); the latter are then organized into chromosomes. *Archaea* also contain histones and nucleosomes, and these are evolutionarily related to those found in *Eukarya*. Moreover, a few *Bacteria* also contain histone-like proteins that function to help organize their DNA.

Only cells of *Eukarya* contain a nucleus. The nucleus is enclosed by a *pair* of membranes, each with its own function, separated by a space. The innermost membrane is a simple sac while the outermost membrane is in many places continuous with the endoplasmic reticulum. The inner and outer nuclear membranes specialize in interactions with the nucleoplasm and the cytoplasm, respectively. The nuclear membranes contain pores (Figures 2.42 and 2.43a), formed from holes where the inner and outer membranes are joined. The pores allow transport proteins to import and export other proteins and nucleic acids into and out of the nucleus, a process called *nuclear transport*.

Within the nucleus is found the *nucleolus* (Figure 2.42), the site of ribosomal RNA (rRNA) synthesis. The nucleolus is rich in RNA, and ribosomal proteins synthesized in the cytoplasm are transported into the nucleolus and combine with rRNA to form the small and large subunits of eukaryotic ribosomes. These are then exported to the cytoplasm, where they associate to form the intact ribosome and function in protein synthesis.

Cell Division

Eukaryotic cell division requires a special process, called **mitosis**, in which the chromosomes are replicated, the nucleus is disassembled, the chromosomes are segregated into two sets, and a nucleus is reassembled in each daughter cell (Figure 2.44). Whereas many (though not all) prokaryotic cells are genetically haploid, microbial eukaryotes often alternate between haploid and diploid states. *Diploid* cells have two copies of each chromosome whereas *haploid* cells have only one. For example, the brewer's yeast *Saccharomyces cerevisiae* can exist in the haploid state (in which cells contain 16 chromosomes) as well as in the diploid state (in which cells contain 32 chromosomes). However, regardless of its genetic state, during cell division the chromosome number is first doubled and later halved to give each daughter cell its correct complement of chromosomes. During mitosis, the chromosomes condense, divide, and are separated into two sets, one for each daughter cell. Each of these distinct stages of nuclear division has a common name used widely in biology: *prophase*, *metaphase*, *anaphase*, and *telophase* (Figure 2.44a–d, respectively).

In contrast to mitosis, **meiosis** converts a diploid cell into several haploid cells. Meiosis consists of two successive cell divisions. In the first meiotic division, pairs of chromosomes segregate into separate cells, changing the genetic state from diploid to haploid. The second meiotic division is essentially the same as mitosis, as the two

Figure 2.43 The nucleus and DNA packaging in eukaryotes. (a) Electron micrograph of a yeast cell prepared in such a way as to reveal a surface view of the nucleus. The cell is about $8\ \mu\text{m}$ wide. (b) Packaging of DNA around histone proteins to form a nucleosome. Nucleosomes are arranged along the DNA strand like beads on a string and aggregate to form chromosomes during the process of mitosis (see Figure 2.44).

haploid cells divide to form a total of four haploid cells called *gametes*. This form of cell division is typically used in organisms that reproduce sexually. In animals, these gametes are the eggs and sperm; in eukaryotic microorganisms, they can be reproductive spores or other reproductive structures.

We now consider the classic organelles of the eukaryotic cell: the mitochondrion and the chloroplast.

Check Your Understanding

- How is DNA arranged in the chromosomes of eukaryotes?
- What are histones and what do they do?
- What are the major differences between mitosis and meiosis?

2.14 Mitochondria and Chloroplasts

Organelles that specialize in energy metabolism in eukaryotes include the mitochondrion and the chloroplast. These organelles have evolutionary roots within the *Bacteria* and provide ATP to the eukaryotic cell either from the oxidation of organic compounds or from light.

Mitochondria

In aerobic eukaryotic cells, respiration occurs in the mitochondrion. **Mitochondria** are the size of a typical bacterium, they have their own DNA and ribosomes, they can take on many shapes (Figure 2.45), and they reproduce independently of the cell. The number of

Chromosomes have separated into the newly forming daughter cells.

Figure 2.45 Structure of the mitochondrion. (a) Diagram showing the overall structure of the mitochondrion; note the inner and outer membranes. (b, c) Transmission electron micrographs of mitochondria from rat tissue showing the variability in morphology; note the cristae. Both mitochondria are about $0.7\ \mu\text{m}$ wide.

mitochondria per cell varies depending on the cell type, its size, and its physiological state. A yeast cell may have only a few mitochondria per cell, whereas an animal cell may have over a thousand. The mitochondrion is enclosed by a double membrane system. Like the nuclear membrane, the outermost mitochondrial membrane is somewhat permeable and contains pores that allow the passage of small molecules. The innermost membrane is much less permeable, and its structure more closely resembles that of the cytoplasmic membrane of *Bacteria*.

Mitochondria also contain folded internal membranes called **cristae**. These membranes, formed by invagination of the inner membrane, contain the enzymes needed for respiration and ATP production. Cristae also contain transport proteins that regulate the passage of key molecules such as ATP into and out of the **matrix**, the innermost compartment of the mitochondrion (Figure 2.45a). The matrix contains enzymes for the oxidation of organic compounds, in particular, enzymes of the citric acid cycle, the major pathway for the combustion of organic compounds to CO_2 (► Section 3.6).

Chloroplasts

Chloroplasts are the chlorophyll-containing organelles found in plants and algae and are the site of photosynthesis. Chloroplasts are

Figure 2.46 Chloroplasts of a diatom and a green alga cell. (a) Fluorescence photomicrograph of a diatom shows chlorophyll fluorescence; arrows, chloroplasts. The cell is about $40\ \mu\text{m}$ wide. (b) Phase-contrast photomicrograph of the filamentous green alga *Spirogyra* showing the characteristic spiral-shaped chloroplasts (arrows) of this phototroph. A cell is about $20\ \mu\text{m}$ wide. (c) Transmission electron micrograph showing a chloroplast of a diatom; note the thylakoids.

about the size of unicellular cyanobacteria and are readily visible with the light microscope (Figure 2.46). Like mitochondria, the number of chloroplasts per cell varies among species, and chloroplasts contain their own DNA and ribosomes.

Also like mitochondria, chloroplasts are enclosed by a double membrane composed of a permeable outer membrane and a less-permeable inner membrane. The innermost membrane surrounds the **stroma**, analogous to the matrix of the mitochondrion (Figure 2.46c). The stroma contains large levels of the enzyme *ribulose biphosphate carboxylase* (RuBisCO), the key enzyme of the *Calvin cycle*, which is the series of biosynthetic reactions by which phototrophs convert CO_2 to organic compounds (► Section 3.12). The permeability of the outermost chloroplast membrane allows glucose and ATP produced during photosynthesis to diffuse into the cell cytoplasm where they are consumed in biosynthesis.

Chlorophyll and all other components needed for ATP synthesis in chloroplasts are located in a series of flattened membrane discs called **thylakoids** (Figure 2.46c). Like the cytoplasmic membrane, the thylakoid membrane is highly impermeable, and its major function is to form a proton motive force (Figure 2.4c) that results in ATP synthesis.

The Endosymbiotic Origin of Organelles

On the basis of their relative autonomy, size, and morphological resemblance to bacteria, it was hypothesized over 100 years ago that mitochondria and chloroplasts were descendants of respiratory

and phototrophic bacterial cells, respectively. According to this hypothesis, when these symbiotic bacteria associated with nonphototrophic hosts, the hosts gained new forms of energy metabolism while the bacterial partners received a stable and supportive growth environment inside the host cell. Then, over time, these originally free-living symbionts became an intimate part of the eukaryotic cell. The idea that symbiotic bacteria are ancestors to the mitochondrion and chloroplast is called the **endosymbiotic theory** and is well accepted in biology today (► Sections 13.4 and 18.1). Several lines of evidence support the endosymbiotic theory. These include, most notably, the fact that mitochondria and chloroplasts contain their own genomes and ribosomes whose structures are similar to the genomes and ribosomes of *Bacteria* but not to those of *Eukarya*. These organellar genomes are also circular, typical of bacterial chromosomes (► Section 10.4).

Eukarya are a distinct domain of life, a domain that evolved after *Bacteria* and *Archaea*. Nevertheless, eukaryotic cells share many genes with both *Bacteria* and *Archaea*. In this respect, *Eukarya* are genetic chimeras that contain genes from two domains of life. The domain *Eukarya* is hypothesized to have originated from a symbiotic fusion between an archaeal host cell and a mitochondrial endosymbiont (derived from *Bacteria*). Sometime later, a second major symbiotic event occurred, in which a eukaryotic host cell acquired a chloroplast endosymbiont (derived from cyanobacteria), becoming the ancestor of all phototrophic eukaryotes (including plants and algae). We consider these important concepts in detail in Chapter 13.

Check Your Understanding

- What key reactions occur in the mitochondrion and in the chloroplast, and what key products are made in each? Why is it important to keep these reactions behind a double membrane?
- What is the endosymbiotic theory, and what evidence is there to support it?

2.15 Other Eukaryotic Cell Structures

Several other complex structures are present within the cytoplasm of microbial eukaryotes in addition to mitochondria and chloroplasts (Figure 2.42). These include the endoplasmic reticulum, the Golgi complex, lysosomes, and a dynamic cytoskeleton. Unlike the nucleus, mitochondria, and chloroplasts, these structures lack both DNA and a double membrane and are not of endosymbiotic origin. In addition, these structures control the transport of proteins and nutrients within the cell and govern cell shape and movement. Cell walls are also present in certain microbial eukaryotes (such as fungi and algae), though there is great diversity in cell wall structure among eukaryotic cells.

Cytoskeleton

The eukaryotic cytoplasm is crisscrossed by a series of dynamic protein filaments, which are used to transport substances, to position cell structures, and to control cell movement. This internal support network consists of *microtubules*, *microfilaments*, and *intermediate filaments*; together, these structures form the cell **cytoskeleton** (Figure 2.42). Some cytoskeleton-like elements are also important for

determining the shape and molecular organization of prokaryotic cells, but the eukaryotic cytoskeleton is notable for its complexity and dynamism.

Microtubules are hollow tubes about 25 nm in diameter and are composed of the proteins α -tubulin and β -tubulin. Microtubules (Figure 2.47a) have many functions including maintaining cell shape and facilitating cell motility, moving chromosomes during mitosis (Figures 2.44 and 2.47b), and in the movement of organelles within the cell. **Microfilaments** (Figure 2.47c) are smaller than microtubules,

Figure 2.47 Tubulin and microfilaments. (a) Fluorescence photomicrograph of a cell of the ciliated protozoan *Tetrahymena thermophila* with red- and green-labeled antitubulin antibodies (the two dyes combine to give yellow) and with DAPI, which stains DNA (blue, nucleus). A cell is about 10 μ m wide. (b) A mouse cell showing the role of tubulin (green) in separating chromosomes (blue) during metaphase of mitosis (cytoplasmic proteins stain red). Compare with Figure 2.44c. (c) Electron microscopic image of the cellular slime mold *Dictyostelium discoideum* showing the network of actin microfilaments that along with microtubules functions as the cell cytoskeleton. Microfilaments are about 7 nm in diameter.

about 7 nm in diameter, and are polymers of two intertwined strands of the protein *actin*. Microfilaments function in maintaining or changing cell shape, in cell motility by cells that move by amoeboid movement, and during cell division. **Intermediate filaments** are fibrous keratin proteins that are arranged into fibers 8–12 nm in diameter and function in maintaining cell shape and positioning organelles in the cell.

Endoplasmic Reticulum, the Golgi Complex, and Lysosomes

The endoplasmic reticulum (ER) is a network of membranes continuous with the nuclear membrane. Two types of endoplasmic reticulum exist: *rough* ER, which contains attached ribosomes, and *smooth* ER, which does not (Figure 2.42). Smooth ER participates in the synthesis of lipids and in some aspects of carbohydrate metabolism. Rough ER, through the activity of its ribosomes, is a major producer of glycoproteins and also produces new membrane material that is transported throughout the cell to enlarge the various membrane systems before cell division.

The Golgi complex is a stack of membrane-bound sacs. In the Golgi complex, products of the ER are chemically modified and sorted into those destined for secretion versus those that will function in other membranous structures in the cell. Many of the modifications made in the Golgi complex are glycosylations (addition of sugar residues) that convert the proteins into glycoproteins that can then be targeted to specific locations in the cell.

Lysosomes (Figure 2.42) are membrane-enclosed compartments that contain digestive enzymes that hydrolyze proteins, fats, and polysaccharides. The lysosome fuses with food that enters the cell in vacuoles and then releases digestive enzymes that break down the foods for biosynthesis and energy generation. Lysosomes also function in degrading damaged cellular components and recycling these materials for new biosyntheses. The lysosome thus allows the cell's lytic activities to be partitioned away from the cytoplasm proper. Following the degradation of macromolecules in the lysosome, the resulting nutrients pass from the lysosome into the cytoplasm for use by cytoplasmic enzymes.

Flagella and Cilia

Flagella and cilia are present on the surface of many eukaryotic microbes and function as motility structures, allowing cells to move by swimming. As we learned when we considered motility in prokaryotic cells (Sections 2.9–2.12), motility has survival value, as the ability to move allows motile organisms to move about their habitat and exploit new resources. *Cilia* are essentially short flagella that beat in synchrony to propel the cell—usually quite rapidly—through the medium. *Flagella*, by contrast, are long appendages present singly or in groups that propel the cell along—typically more slowly than

Figure 2.48 Motility organelles in eukaryotic cells: Flagella and cilia. (a) Flagella can be present as single or multiple filaments. Cilia are structurally similar to flagella but much shorter. Eukaryotic flagella move in a whiplike motion. (b) Cross section through a flagellum of the fungus *Blastocladiella* showing the outer sheath, the outer nine pairs of microtubules, and the central pair of microtubules.

by cilia—through a whiplike motion (Figure 2.48a). In cross section, eukaryotic cilia and flagella appear similar. Each contains a bundle of nine pairs of microtubules surrounding a central pair of microtubules (Figure 2.48b). A protein called *dynein* is attached to the microtubules and uses ATP to drive motility. Movement of flagella and cilia is similar. In both cases, movement is the result of the coordinated sliding of microtubules against one another in a direction toward or away from the base of the cell. This movement confers the whiplike motion on the flagellum or cilium that results in cell propulsion.

Eukaryotic flagella differ structurally and functionally from the flagella of *Bacteria* and the archaeella of *Archaea*, and these three structures should not be confused (contrast Figure 2.48 with Figure 2.34). Eukaryotic flagella are much larger than flagella or archaeella, are enclosed by the cytoplasmic membrane and contain a cytoskeleton, and do not rotate but rather whip back and forth through the activity of their cytoskeleton proteins.

Armed with the major principles of microbial cell structure and function, we move on to Chapter 3 where the metabolic events that provide the energy necessary to build cellular components will unfold as a prelude to our consideration of the building process itself.

Check Your Understanding

- Why are the activities in the lysosome partitioned from the rest of the cytoplasm?
- Describe the structural elements that comprise the cytoskeleton.
- In terms of structure and function, how do the flagella of eukaryotic cells differ from those of prokaryotic cells?

CHAPTER REVIEW

I • The Cell Envelope

- 2.1** The cytoplasmic membrane is a highly selective permeability barrier constructed of lipids and proteins that form a bilayer, with a hydrophobic interior and hydrophilic exterior. In contrast to *Bacteria* and *Eukarya*, where fatty acids are ester-linked to glycerol, *Archaea* contain ether-linked lipids, and some form monolayer instead of bilayer membranes. The major functions of the cytoplasmic membrane are permeability, transport, and energy conservation, and nutrient accumulation requires energy.

Q Does the cytoplasmic membrane of prokaryotic cells provide shape and rigid support to the cell? Contrast the typical structure of the cytoplasmic membranes of *Bacteria* and *Archaea*.

- 2.2** The active transport of nutrients into the cell is an energy-requiring process driven by ATP (or some other energy-rich compound) or by the proton motive force. Three transporters are employed by prokaryotic cells: simple, group translocation, and ABC systems. Each mechanism accumulates solutes against the concentration gradient.

Q Cells of *Escherichia coli* transport lactose via lac permease, glucose via the phosphotransferase system, and maltose via an ABC-type transporter. For each of these sugars describe: (1) the components of the transport system and (2) the source of energy that drives the transport event.

- 2.3** Peptidoglycan is a polysaccharide found only in *Bacteria* that consists of an alternating repeat of *N*-acetylglucosamine and *N*-acetylmuramic acid, the latter cross-linked by tetrapeptides in adjacent strands. The enzyme lysozyme and the antibiotic penicillin both destroy peptidoglycan, leading to cell lysis.

Q Why is the rigid layer of the bacterial cell wall called peptidoglycan? What are the structural reasons for the rigidity that is conferred on the cell wall by the peptidoglycan structure?

- 2.4** Gram-negative *Bacteria* have an outer membrane consisting of LPS, protein, and lipoprotein. Porins allow for permeability across the outer membrane. The gap between the outer and cytoplasmic membranes is called the periplasm and contains proteins that function in transport, sensing chemicals, and other important cell functions.

Q Is the outer membrane more selective or less selective than the cytoplasmic membrane? Describe the periplasm and its possible functions.

- 2.5** Cell envelopes can exhibit a range of different structures. One common variation is the presence of an outer S-layer composed of protein or glycoprotein. S-layers function as the cell wall for many *Archaea* and they are also found in many *Bacteria*.

Q What functions can S-layers provide to those cells that make them?

II • Cell Surface Structures and Inclusions

- 2.6** Many prokaryotic cells have capsules, slime layers, or pili. These structures have several functions, including attachment, genetic exchange, and twitching motility. Hami, present on the surface of certain *Archaea*, function as miniature grappling hooks to attach cells to a surface or to one another.

Q What function(s) do polysaccharide layers outside the cell wall have in prokaryotic cells?

- 2.7** Prokaryotic cells can contain inclusions of sulfur, polyphosphate, carbon polymers, various minerals formed by biomineralization, or atmospheric gases. These substances function as nutrient storage materials, control magnetotaxis (in the case of magnetosomes), or confer buoyancy (in the case of gas vesicles).

Q What are some of the roles of poly- β -hydroxyalkanoates (PHAs)?

- 2.8** The endospore is a highly resistant and differentiated structure produced by certain gram-positive *Bacteria*. Endospores are highly dehydrated and contain calcium dipicolinate and small acid-soluble spore proteins, both of which are absent from vegetative cells. Endospores can remain dormant indefinitely but can germinate quickly when conditions warrant.

Q Is an endospore still the same bacterial cell? What are the different types of endospores as to their location in the cell? Describe the structure of endospores.

III • Cell Locomotion

- 2.9** Swimming motility in prokaryotic cells is due to flagella (*Bacteria*) or archaella (*Archaea*). Both structures are composed of several proteins, are anchored in the cell wall and cytoplasmic membrane, and cause cells to swim by their rotation. However, flagella and archaella differ in both structure and mechanism of operation.

Q Compare and contrast the differences in structure and mechanism between the flagella of *Bacteria* and the archaella of *Archaea*.

- 2.10** Some microbes are capable of surface motility in which they move along solid surfaces by one of several mechanisms including twitching or gliding.

Q Contrast the mechanisms of gliding motility in *Flavobacterium* with twitching motility in *Pseudomonas* and swimming motility in *Escherichia coli*.

- 2.11** Swimming bacteria respond to chemical and physical gradients in their environment by controlling the lengths of runs and frequency of tumbles, resulting in a biased random walk. Tumbles are controlled by the direction of rotation of the flagellum, which in turn is controlled by a network of sensory and response proteins.

Q Chemotaxis causes motile bacteria to either move towards attractants or move away from repellents. Movement is determined by coordinated runs and tumbles, leading to biased random walks in response to the concentration of the chemotactic chemical. How would simple diffusion of an attractant over time affect the biased random walk?

- 2.12** Phototaxis describes directed motility in response to light intensity, while scotophobotaxis describes directed motility away from the dark. Aerotaxis describes directed motility in response to O₂ gradients.

Q Magnetotactic bacteria do not exhibit directed motility in response to magnetic fields and hence their name is a misnomer. Describe the role of magnetosomes and aerotaxis in the directed movements of magnetotactic bacteria.

IV • Eukaryotic Microbial Cells

- 2.13** Microbial eukaryotes contain several organelles including the nucleus, mitochondria, and chloroplasts. The nucleus contains the cell's DNA wrapped around histone proteins. Cells of microbial eukaryotes divide following the process of mitosis and may also undergo meiosis if a haploid/diploid life cycle occurs.

Q Eukaryotic cell division's aim is to create two identical, functional daughter cells. Hence, the DNA in the parent cell is replicated so that both daughter cells receive a full set of chromosomes. Do other organelles such as mitochondria, endoplasmic reticulum, etc. in the cytoplasm and cell membrane need to be replicated too? Explain.

- 2.14** Mitochondria and chloroplasts are energy-generating organelles. According to the endosymbiotic theory, these organelles were once free-living *Bacteria* that later established symbiotic relationships within ancestral cells of *Eukarya*.

Q Describe the evidence that supports the idea that the major organelles of eukaryotes were once *Bacteria*.

- 2.15** Endoplasmic reticula are membranous structures in eukaryotes that either contain attached ribosomes (rough ER) or do not (smooth ER). Flagella and cilia are means of motility and in eukaryotic cells move by a whiplike mechanism instead of by rotation. Lysosomes specialize in degrading proteins and other macromolecules no longer needed by the cell. Microtubules, microfilaments, and intermediate filaments function as internal cell structures that combine to form the cell cytoskeleton.

Q Compare and contrast the structure and function of eukaryotic flagella with those of prokaryotic cells.

APPLICATION QUESTIONS

1. Assume you are given two cultures, one of a species of gram-negative *Bacteria* and one of a species of *Archaea*. Discuss at least four different ways you could analyze these two cultures and tell which culture was which.
2. Gram-negative and gram-positive bacteria have different susceptibility to antibiotics because of differences in cell

envelope structure. Assume that you are given an antibiotic that is effective against gram-positive cells but ineffective against gram-negative cells because it cannot cross the outer membrane. How might you chemically modify this antibiotic to increase its efficacy against gram-negative organisms?

CHAPTER GLOSSARY

ABC transport system a membrane transport system consisting of three proteins, one of which hydrolyzes ATP; the system transports specific nutrients into the cell

Archaeum a long, thin cellular appendage present in some *Archaea* that rotates and is responsible for swimming motility

Basal body the "motor" portion of the bacterial flagellum, embedded in the cytoplasmic membrane and cell wall

Capsule a polysaccharide or protein outermost layer, usually rather slimy, present on some bacteria

Cell envelope the system of layered structures that surround the cytoplasm and define the outer boundary of the cell

Chemotaxis directed movement of an organism toward (positive chemotaxis) or away from (negative chemotaxis) a chemical gradient

Chloroplast the photosynthetic organelle of phototrophic eukaryotes

Cristae the internal membranes of a mitochondrion

Cytoplasmic membrane a semipermeable barrier that separates the cell interior (cytoplasm) from the environment

Cytoskeleton the cellular scaffolding typical of eukaryotic cells, made of microtubules, microfilaments, and intermediate filaments

Dipicolinic acid a substance unique to endospores which, when complexed with

Ca²⁺, confers heat resistance on these structures

Endospore a highly heat-resistant, thick-walled, differentiated structure produced by certain gram-positive *Bacteria*

Endosymbiotic theory the idea that mitochondria and chloroplasts originated from *Bacteria*

Flagellum a long, thin cellular appendage that rotates in *Bacteria* or has a whiplike motion in *Eukarya* and is responsible for swimming motility

Gas vesicles gas-filled cytoplasmic structures bounded by a single layered protein membrane that confer buoyancy on cells

Gliding motility a form of surface motility characterized by smooth continuous movement

Group translocation an energy-dependent transport system in which the substance transported is chemically modified during the process of being transported by a series of proteins

Histones highly basic proteins that compact and wind DNA in the nucleus of eukaryotic cells

Intermediate filament a filamentous polymer of fibrous keratin proteins, supercoiled into thicker fibers, that functions in maintaining cell shape and the positioning of certain organelles in the eukaryotic cell

Lipopolysaccharide (LPS) a combination of lipid with polysaccharide and protein that forms the major portion of the outer membrane in gram-negative *Bacteria*

Lysosome an organelle containing digestive enzymes for hydrolysis of proteins, fats, and polysaccharides

Magnetosome a particle of magnetite (Fe_3O_4) or greigite (Fe_3S_4) enclosed by a single membrane in the cytoplasm of magnetotactic *Bacteria*

Meiosis the nuclear division that halves the diploid number of chromosomes to the haploid

Microfilament a filamentous polymer of the protein actin that helps maintain the shape of a eukaryotic cell

Microtubule a filamentous polymer of the proteins α -tubulin and β -tubulin that functions in eukaryotic cell shape and motility

Mitochondrion the respiratory organelle of eukaryotic organisms

Mitosis nuclear division in eukaryotic cells in which chromosomes are replicated and partitioned into two daughter cells during cell division

Nucleus a membrane-enclosed structure in eukaryotic cells that contains the cell's DNA genome

Outer membrane a phospholipid- and polysaccharide-containing unit membrane that lies external to the peptidoglycan layer in cells of gram-negative *Bacteria* and is a component of the cell envelope in these organisms

Peptidoglycan a polysaccharide composed of alternating repeats of *N*-acetylglucosamine and *N*-acetylmuramic acid arranged in adjacent layers cross-linked by short peptides; a component of the cell envelope of virtually all *Bacteria*

Periplasm a region between the outer surface of the cytoplasmic membrane and the inner surface of the lipopolysaccharide layer of gram-negative *Bacteria*

Peritrichous flagellation having flagella located in many places around the surface of the cell

Phototaxis movement of an organism toward light

Pili thin, filamentous structures that extend from the surface of a cell and, depending on type, facilitate cell attachment, genetic exchange, or twitching motility

Polar flagellation having flagella emanating from one or both poles of the cell

Poly- β -hydroxybutyric acid (PHB) a common storage material of prokaryotic cells consisting of a polymer of β -hydroxybutyrate or another β -alkanoic acid or mixtures of β -alkanoic acids

S-layer an outermost cell surface layer composed of protein or glycoprotein present on some *Bacteria* and many *Archaea*

Simple transport system a transporter that consists of only a membrane-spanning protein and is typically driven by energy from the proton motive force

Stroma the lumen of the chloroplast, surrounded by the inner membrane

Teichoic acid a phosphorylated polyalcohol found in the cell wall of some gram-positive *Bacteria*

Thylakoids membrane stacks containing the photosynthetic pigments in cyanobacteria or in the chloroplast of eukaryotic phototrophs

Twitching motility a form of surface motility caused by extension and retraction of type IV pili

Microbial Metabolism 3

MICROBIOLOGYNOW

Life Begins with Metabolism

Metabolism is the foundation upon which life is formed. Microorganisms have evolved tremendous metabolic diversity, but all microbes in their vast diversity have a common set of requirements. Life requires liquid water, a source of energy to do work, a source of electrons to perform biochemical reactions, and nutrients required to build macromolecules. Once we understand these requirements, we can begin to make predictions about how life behaves in any environment, whether a caustic hypersaline pond, inside a rock from the cold deserts of Antarctica, in a hydrothermal vent chimney from the ocean's depths, or even on another world. In short, the search for life begins with an understanding of metabolism.

Water is common in our solar system. There is water on Mars and on Earth's moon, on asteroids and comets, and there is evidence for water on several other planets and moons. Liquid water, however, is harder to find. One place that has liquid water is the moon Enceladus, which orbits Saturn. Enceladus has an ice-covered ocean with cracks in

its surface through which erupt geysers that spew materials into space (see photo). The Cassini spacecraft photographed and flew through these plumes, detecting silicate minerals that form only in the presence of liquid water.

The gravity from Saturn squeezes Enceladus, resulting in volcanic activity and liquid water beneath its icy crust. These plumes also contain diverse organic and inorganic compounds and the gases H_2 , CO_2 , and methane (CH_4). Taken as a whole, these molecules are sufficient to provide free energy, a source of electrons, and nutrients required to support life. Indeed, microbes could likely survive at the hydrothermal vents thought to exist on Enceladus. We now know that all of the fundamental requirements for life are present on other worlds, and the search for extraterrestrial life is a search for microbial life.

- I Fundamentals of Metabolism 112
- II Catabolism: Chemoorganotrophs 121
- III Catabolism: Electron Transport and Metabolic Diversity 130
- IV Biosynthesis 134

Metabolism is the series of biochemical reactions needed to sustain life. Metabolism includes **catabolism**—reactions used to obtain energy and break down complex molecules—and **anabolism**—reactions used to synthesize cellular material (Figure 3.1). Microorganisms have evolved tremendous metabolic diversity through which they influence all aspects of our biosphere. In this chapter, we will learn the unifying concepts of metabolism that underlie all living systems. In particular, we will examine the manner in which cells obtain energy and how they use this energy to synthesize the building blocks of macromolecules and cells (Figure 3.1a). We will also see that metabolism relies on the directed movement of electrons from an *electron donor* to an *electron acceptor* (Figure 3.1b). We will revisit these principles of metabolism in Chapter 6, where we explore the biosynthesis of macromolecules—the nucleic acids and proteins—and in Chapter 14, where the enormous metabolic diversity of the microbial world unfolds.

I • Fundamentals of Metabolism

Bioenergetics describes the transformation of energy during metabolism characterized by electron flow within the cell. Metabolism uses the energy currency of ATP to couple the exergonic reactions of catabolism to the endergonic reactions of anabolism.

According to the first law of thermodynamics, energy is neither created nor destroyed. Hence, in order to grow, cells must *conserve energy* by converting energy available from their surroundings into a form that can do work. Cells accomplish this by generating energy-rich compounds such as *adenosine triphosphate* (ATP)—a molecule capable of storing energy and releasing it to fuel cellular processes (Figure 3.1).

3.1 Defining the Requirements for Life

All living cells share certain fundamental metabolic requirements. All cells require *water* in which to perform metabolic reactions, as well as sources of *carbon* and other *nutrients* with which to synthesize cellular materials. All cells also require **free energy**—the *energy available to do work*—and **reducing power**—a source of electrons (e^-) that can be used to both generate free energy and perform

certain biosynthetic reactions (Figure 3.1). We will review the nutrient requirements of cells in Chapter 4. Here we will learn to categorize and understand all forms of metabolism in terms of free energy and reducing power.

Free Energy

All chemical reactions can be described in terms of their relationship to energy. Some chemical reactions *release energy* as they proceed, while others *require an input of energy* to proceed. Consider the reaction for the aerobic respiration of glucose:

In this reaction the reactants are on the left ($C_6H_{12}O_6 + 6 O_2$) and the products are on the right ($6 CO_2 + 6 H_2O$). The *change* in free energy during a reaction is expressed as $\Delta G^{0'}$, where the symbol Δ is read as “change in.” The “0” and “prime” in $\Delta G^{0'}$ indicate that the free-energy value is for *standard conditions*: pH 7 (approximate cytoplasmic conditions), 25°C, 1 atmosphere of pressure, and all reactants and products at molar concentrations. The term $\Delta G^{0'}$ is expressed in units of kilojoules/mole (abbreviated as kJ/mol), a unit of heat energy. If the $\Delta G^{0'}$ for a reaction is *negative* in arithmetic sign, then the reaction will proceed with the *release* of free energy and such reactions are **exergonic**. However, if $\Delta G^{0'}$ for the reaction is *positive*, the reaction *requires* energy in order to proceed and such reactions are **endergonic**. Thus, exergonic reactions *release* free energy whereas endergonic reactions *require* free energy. For example, the aerobic respiration of glucose provides a free-energy change of $\Delta G^{0'} = -2895$ kJ/mol of glucose. Hence, this reaction is exergonic and it provides a substantial amount of free energy that can be used by the cell to do work. We will learn how to calculate the free-energy change of a reaction in Section 3.3.

Catabolic pathways are exergonic processes in which cells generate free energy by transforming reactants into products (Figure 3.1a). Free energy is energy available to do work. The free energy produced in catabolism is conserved by synthesizing energy-rich molecules such as ATP (Figure 3.1a). The formation of ATP requires at least $\Delta G^{0'} = -31.8$ kJ/mol. Hence, the aerobic respiration of a mole of glucose could produce up to 91 moles of ATP under standard conditions, though under natural cellular conditions this reaction actually produces closer to 38 moles of ATP. This difference in ATP yield occurs because reactions in the cell do not occur under standard

Figure 3.1 Metabolic coupling with respect to energy conservation and electron flow. (a) Catabolism employs exergonic reactions to drive the synthesis of ATP. Anabolism employs endergonic reactions, which consume ATP, to drive the biosynthesis of cellular material. Some energy would be lost as heat and cannot be conserved in the formation of ATP (not shown). (b) Cells require reducing power, in the form of a reduced electron donor, as a source of electrons (e^-) needed to carry out anabolic and catabolic reactions. Inputs to metabolism are labeled in {green} and outputs of metabolism are labeled in {yellow}.

conditions. We will see in Section 3.3 that the free energy available under natural conditions differs from the free energy calculated at standard conditions. In addition, chemical reactions release some portion of energy in the form of heat, which cells cannot conserve in the formation of ATP. The heat lost during metabolic reactions is what makes your body warm and what makes a decomposing compost pile become steaming hot.

Anabolic pathways are endergonic processes in which the synthesis of cellular material from simple precursors requires an input of energy (Figure 3.1a). The energy required to fuel anabolic reactions, and to biosynthesize cellular materials, comes from the hydrolysis of ATP. In this way, catabolic and anabolic reactions are fundamentally linked (Figure 3.1a).

Reducing Power

Reducing power is the ability to donate electrons during electron transfer reactions. Electron transfer reactions, called **redox reactions**, are comprised of two half reactions. During redox reactions, electrons are transferred from an **electron donor** in one half reaction to an **electron acceptor** in a second half reaction. When an electron is added to a substance, we say that the substance has been *reduced* because the addition of an electron reduces the oxidation state of the substance. In contrast, when an electron is removed from a substance we say it has been *oxidized* (Figure 3.1b). Consider again the aerobic respiration of glucose (Figure 3.2). In this example, which is a redox reaction, glucose is the electron donor and O_2 is the electron acceptor. Electrons are transferred from glucose to O_2 , resulting in the oxidation of glucose to CO_2 and the reduction of O_2 to H_2O (Figure 3.2). Redox reactions are an essential component of catabolism, and we will see that they are integral to energy conservation within the cell.

Reducing power is also required by anabolic reactions (Figure 3.1b). The biosynthesis of cellular materials from simple precursors requires both free energy, in the form of ATP, and reducing power, in the form of electron carriers that transfer electrons to anabolic reactions. We will learn more about the metabolic significance

Figure 3.2 Example of an oxidation–reduction reaction. The oxidation of glucose to CO_2 is coupled with the reduction of O_2 to H_2O in aerobic chemoorganotrophic organisms. This redox reaction is composed of two half reactions: $CO_2/\text{glucose}$ and $\frac{1}{2} O_2/H_2O$ (see Figure 3.4). The overall reaction is balanced, which means that equal amounts of each element (C, H, O) are present in reactants and products. The complete oxidation of one glucose to $6 CO_2$ donates 24 electrons, which are accepted by $6 O_2$.

of electron carriers and redox reactions in Section 3.2. First, we consider how different organisms obtain the free energy they need to drive ATP synthesis.

Metabolic Classes of Microorganisms

All types of metabolism can be classified based on their source of energy (Figure 3.3). **Phototrophs** obtain energy for metabolism from light. Plants are one type of phototroph, but we will learn that many different types of phototrophic metabolism exist in the microbial world (see Section 3.11 and Chapters 14 and 15). **Chemotrophs** obtain energy for metabolism from chemical reactions (Figure 3.3). The aerobic respiration of glucose is an example of chemotrophic metabolism in that free energy comes from the chemical oxidation of glucose to CO_2 (Figures 3.2 and 3.3). Chemotrophic reactions are classified as *aerobic* if they require O_2 as an electron acceptor, but they are classified as *anaerobic* if their electron acceptor is anything other than O_2 (see Section 3.10). Chemotrophs can conserve energy from either *respiration* reactions or *fermentation* reactions (see Sections 3.7–3.9). For example, in the presence of O_2 , yeast can perform aerobic respiration of glucose to CO_2 , but when O_2 is limiting they alter their metabolism to perform anaerobic fermentation of glucose to ethanol and CO_2 .

The ultimate source of energy for chemotrophic organisms can be *organic* or *inorganic*. Organic molecules are those molecules that contain carbon, excluding certain carbon-containing gases and minerals considered inorganic (for example, compounds such as CO_2 , CO, carbonates, cyanides, diamond, and graphite are considered inorganic). Organisms that obtain their energy and reducing power from organic molecules are called **chemoorganotrophs** while those that obtain their energy and reducing power from inorganic molecules

Figure 3.3 Classification of metabolic types based on energy sources.

Microorganisms can obtain energy from organic chemicals, inorganic chemicals, or light. Most organisms employ only one type of metabolism, but some microbes can use different energy sources depending on environmental conditions.

are called **chemolithotrophs** (Figure 3.3). Most microorganisms in laboratory culture, and most pathogenic bacteria, use carbohydrates or proteins as their energy source and are thus chemoorganotrophs. Chemolithotrophs, by contrast, are important in many biogeochemical cycles. Electron donors for chemolithotrophs include gaseous hydrogen (H_2), hydrogen sulfide (H_2S), ammonia (NH_3), and ferrous iron (Fe^{2+}). Related groups of chemolithotrophs typically specialize in the oxidation of a group of similar inorganic compounds, and thus we have the “sulfur” bacteria, the “iron” bacteria, the “nitrifying” bacteria, and so on (see Chapters 14 and 15).

Phototrophs contain chlorophylls and other pigments that convert light energy into ATP and thus, unlike chemotrophs, do not require chemicals as a source of energy (Section 3.11). Two forms of phototrophy exist: *oxygenic photosynthesis* and *anoxygenic photosynthesis*. Oxygenic photosynthesis, in which O_2 is produced, is characteristic of cyanobacteria (► Section 15.3) and is also carried out by plants and algae. Anoxygenic photosynthesis (► Section 14.5), in which O_2 is not produced, predates oxygenic photosynthesis, and it occurs in diverse lineages of *Bacteria*. We explore the diversity of phototrophs further in Chapters 14 and 15.

Regardless of how a microorganism conserves energy, be it from chemicals or from light, all cells require large amounts of carbon in one form or another to make new cell materials. A **heterotroph** obtains carbon for biosynthesis from an organic compound; nearly all chemoorganotrophs are also heterotrophs. An **autotroph**, by contrast, uses carbon dioxide (CO_2) as its carbon source, reducing it to cell material at the expense of ATP (Section 3.12). Most chemolithotrophs and phototrophs are autotrophs. Autotrophs are also called *primary producers* because they synthesize new organic matter from inorganic carbon (CO_2). Virtually all organic matter on Earth has been synthesized by primary producers, in particular, by phototrophs.

We now expand on this introduction to metabolism and energy by emphasizing electron transfer reactions, energy-rich compounds, and enzymes in the biochemical workings of a cell.

3.2 Electron Transfer Reactions

Catabolism, and indeed life itself, depends on the directed flow of electrons from an *electron donor* to an *electron acceptor* during redox reactions (Figure 3.1b). Redox reactions are also required in many biosynthetic reactions that occur during anabolism (Sections 3.12–3.15). Redox reactions can be understood in terms of *reduction potential* (Figure 3.4), which measures the affinity of a substance for electrons.

Redox Reactions and Reduction Potentials

Although life requires the transfer of electrons within the cell, electrons cannot exist stably in solution. Therefore, electrons must be transferred directly from one atom or molecule to another during

Figure 3.4 The redox tower. Redox couples are arranged from the strongest electron donors at the top to the strongest electron acceptors at the bottom. The greater the difference in reduction potential between electron donor and electron acceptor, the greater the free energy released. Note the differences in free-energy yield when glucose reacts with either O_2 (1) or nitrate (2).

redox reactions. Redox reactions occur in pairs, called *half reactions* (also called *redox couples*). A half reaction depicts the conversion of one substance into another caused by adding or removing electrons. By convention, in writing a half reaction, the *oxidized* form of a substance is always placed on the left (before the forward slash) followed by the *reduced* form after the forward slash (Figure 3.4). For example, the addition of an electron to nitrate (NO_3^-) causes it to be reduced to nitrite (NO_2^-) and so we write this redox couple as $\text{NO}_3^-/\text{NO}_2^-$ (Figure 3.4).

In a redox reaction the first half reaction produces one or more electrons that are then consumed by the second half reaction. The reactant in the first half reaction donates electrons and is *oxidized*, whereas the reactant in the second half reaction accepts these electrons and is *reduced*. In redox reactions of this type, we refer to the reactant that is *oxidized* as the *electron donor*, and the reactant that is *reduced* is the *electron acceptor*. Consider the redox reaction between glucose and O_2 (Figure 3.2). The two half reactions that contribute to this overall reaction are $\text{CO}_2/\text{glucose}$ and $\frac{1}{2} \text{ O}_2/\text{H}_2\text{O}$ (Figure 3.4). In this reaction, glucose is oxidized to CO_2 , causing the reduction of O_2 to H_2O . Both glucose and O_2 are reactants in the overall reaction with glucose serving as electron donor and O_2 serving as electron acceptor. The products of this reaction are CO_2 and H_2O . Many

different redox couples exist in nature (Figure 3.4 and Table 3.1) and can participate in diverse redox reactions within the cell.

All redox couples have the ability to either donate or accept electrons to another redox couple. Within each redox couple, the reduced substance (which occurs after the forward slash) is the chemical form that donates electrons, and the oxidized substance (which occurs before the forward slash) is the form that accepts electrons. Whether a substance is an electron donor or an electron acceptor in a given redox reaction is determined by the **reduction potential** (E_0' at standard conditions) of the participating half reactions (Figure 3.4 and Table 3.1). Reduction potentials are measured in volts (V) compared to a reference substance (typically, the reference is H₂). Electrons are negatively charged and so the *reduced* substance in a redox couple will have a strong tendency to *donate* electrons when the redox couple has a negative reduction potential (for example, glucose in the CO₂/glucose couple, $E_0' = -0.43$ V). In contrast, the *oxidized* substance in a redox couple will have a strong tendency to *accept* electrons when the redox couple has positive reduction potential (for example, O₂ in the $\frac{1}{2}$ O₂/H₂O couple, $E_0' = +0.82$ V). Ultimately, the tendency of a substance to donate or accept electrons in a redox reaction is determined by the difference in reduction potential between the two participating redox couples. In a given redox couple the substance on the right is the chemical form that serves as an electron donor in a redox reaction, while the substance on the left is the chemical form that serves as an electron acceptor.

By convention, half reactions are written as reductions (as in Figure 3.4 and Table 3.1). However, when two half reactions are combined into a single redox reaction the half reaction that donates electrons (that is, the half reaction with the more negative E_0') proceeds as an oxidation, and its orientation is therefore written in reverse (as an oxidation) in the overall redox reaction. For example, the CO₂/glucose couple has a far more negative reduction potential than the $\frac{1}{2}$ O₂/H₂O couple, a difference of 1.25 V (Figure 3.4). Hence, in the redox reaction that includes these two couples, glucose is the electron donor and its half reaction is written as an oxidation, with the net reaction having the reactants glucose and O₂ and the products CO₂ and H₂O (Figures 3.2 and 3.4).

When aerobic respiration is prevented by the absence of O₂, some organisms can carry out anaerobic respiration using an alternative electron acceptor, such as nitrate (see Section 3.10). Nitrate (NO₃[−]) is the oxidized substance in the NO₃[−]/NO₂[−] redox couple ($E_0' = 0.42$ V). The CO₂/glucose couple has a more negative reduction potential than the NO₃[−]/NO₂[−] couple, a difference of 0.85 V (Figure 3.4). Hence, glucose will serve as a favorable electron donor with nitrate as the electron acceptor (see Figure 3.4 for the balanced reaction). The positive difference in reduction potential of the two half reactions indicates that this will be a favorable reaction, though because there is less difference in reduction potential (0.85 V relative to 1.25 V), the anaerobic respiration of glucose using NO₃[−] as electron acceptor yields less energy than aerobic respiration (Figure 3.4).

In this way, reduction potentials can be used to determine whether any given substance in a half reaction will serve as electron donor or electron acceptor in an overall redox reaction. In addition, *the greater the difference in the reduction potentials of the two half reactions in a redox couple, the more energy will be available to the cell*. A vast diversity of redox couples exist in nature, allowing for a tremendous diversity of redox reactions (Figure 3.4 and Table 3.1). We will see that microbes have evolved to harness energy from a large number of redox reactions, giving rise to the astounding metabolic diversity present in the microbial world (Chapters 14 and 15). We will learn in Section 3.3 how to use the difference in reduction potential between two half reactions to calculate the overall free-energy yield of a reaction.

Electron Carriers and NAD⁺/NADH Cycling

Cells require a net movement of electrons from an electron donor to an electron acceptor, but such reactions are rarely performed in a single step. More often, the movement of electrons from electron donor to electron acceptor proceeds through a series of consecutive reactions at different locations within the cell. Hence, the cell needs soluble electron carriers such as **nicotinamide adenine dinucleotide** (NAD⁺/NADH) to carry electrons from one place to another within the cell (Figure 3.5). NAD⁺/NADH is a redox couple with a reduction potential of −0.32 V, which makes NADH a good electron donor and NAD⁺ a weak electron acceptor (Figure 3.4). The reduction of NAD⁺ to NADH requires 2 e[−] and 1 H⁺, but the

Figure 3.5 The redox coenzymes nicotinamide adenine dinucleotide (NAD⁺) and NADP⁺. NAD⁺ undergoes oxidation–reduction as shown and is freely diffusible. “R” is the adenine dinucleotide portion of NAD⁺; H is hydrogen (consisting of H⁺ + e⁻).

oxidation of electron donors typically results in the production of 2 e⁻ and 2 H⁺. Therefore, the reduction of NAD⁺ typically results in the production of NADH + H⁺ with the extra proton released into solution (Figure 3.5).

Electron carriers such as NAD⁺/NADH are common *coenzymes* (see Section 3.5) in cells. The use of electron carriers as coenzymes increases the diversity of redox reactions that are possible in a cell by allowing many different electron donors and acceptors to interact. For example, an enzyme can remove electrons from an electron

donor and use them to reduce NAD⁺ to NADH (Figure 3.6). The NADH then diffuses away from the enzyme and attaches to a different enzyme that oxidizes NADH back to NAD⁺ when it reduces an electron acceptor (Figure 3.6).

Electron shuttling mediated by NAD⁺/NADH is common in microbial catabolism. However, in addition to NAD⁺/NADH, many other molecules may participate as electron shuttles. For example, nicotinamide adenine dinucleotide phosphate (NADP⁺) is made from NAD⁺ by adding a phosphate molecule (Figure 3.5). We will see that NADP⁺/NADPH participates in many anabolic biosynthetic reactions, whereas NAD⁺/NADH typically participates in catabolic redox reactions.

Check Your Understanding

- Can both glucose and H₂S be used to reduce NAD⁺? Why or why not?

3.3 Calculating Changes in Free Energy

We have seen that cells conserve energy from chemical reactions or from light, and they transfer electrons from electron donors to electron acceptors by using electron carriers such as NADH. Ultimately, in order to conserve energy, cells need to synthesize energy-rich molecules such as ATP. We will see that numerous (but not all) electron transfer reactions are sufficiently exergonic to produce ATP and thus can support a vast diversity of microbial metabolisms. However, to better understand this diversity in metabolism, we once again return

to the concept of reduction potential and this time place it in the context of free-energy change.

The Redox Tower and Its Relationship to $\Delta G^{0'}$

A convenient way of viewing the energy available in electron transfer reactions is to imagine a vertical tower that represents the entire range of reduction potentials possible for redox couples in nature, from those with the most negative E_0' on the top to those with the most positive E_0' at the bottom; this is a *redox tower* (Figure 3.4). Now imagine electrons from an electron donor near the top of the tower falling and being “caught” by electron acceptors at lower levels. The difference in reduction potential between the donor and acceptor redox couples is expressed as $\Delta E_0'$, the change in reduction potential. For example, we have seen that the oxidation of glucose with O_2 as electron acceptor yields far more energy than when nitrate (NO_3^-) is the electron acceptor (Section 3.2 and Figure 3.4).

The further an electron drops before it is caught by an acceptor, the greater is the $\Delta E_0'$ between the two redox couples and the greater is the amount of energy released in the net reaction. That is, $\Delta E_0'$ is proportional to $\Delta G^{0'}$ (Figure 3.4). This relationship is expressed more precisely in the equation $\Delta G^{0'} = -nF\Delta E_0'$, where n is the number of electrons transferred and F is the Faraday constant (96.5 kJ/V). Hence, we can see that redox reactions provide a source of energy to the cell and that the greater the difference in reduction potential between electron donor and electron acceptor, the greater the energy available to the cell. This is illustrated for an example reaction, the oxidation of acetate to CO_2 , in equation 1 of Table 3.2.

Calculating $\Delta G^{0'}$ from the Free Energy of Formation

There is a second way to calculate $\Delta G^{0'}$ if one knows the *free energy of formation* (G_f^0) of the reactants and products in the reaction. The free energy of formation is equal to the energy released or required during the formation of a given molecule from its constituent elements. Table 3.3 lists the G_f^0 for a few common substances. By convention, the free energy of formation of the *elements* in their elemental and electrically neutral form (for instance, C, H_2 , N_2) is zero. For most compounds, G_f^0 is negative. This reflects the fact that

TABLE 3.2 Example of free-energy-change calculations using electrochemical potentials or G_f^0 values

For the reaction in which acetate is oxidized completely to CO_2 :^a

1. Calculation from E_0' values:^b

$$\begin{aligned}\Delta G^{0'} &= -nF\Delta E_0' \\ &= [-8(96.5)(1.1)] \\ &= -849 \text{ kJ/reaction}\end{aligned}$$

2. Calculation from G_f^0 values:

$$\begin{aligned}\Delta G^{0'} &= [G_f^0(\text{products}) - G_f^0(\text{reactants})] \\ &= [G_f^0(2 CO_2 + 2 H_2O) - G_f^0(CH_3COO^- + H^+ + 2 O_2)] \\ &= -852 \text{ kJ/reaction}\end{aligned}$$

^aThe reaction is balanced and is an 8-electron oxidation ($n = 8$ in equation 2). G_f^0 values were taken from Table 3.3.

^b F is the Faraday constant (96.5 kJ/V) and $\Delta E_0'$ is calculated from the E_0' values in Figure 3.4 and Table 3.1.

compounds tend to form spontaneously (that is, with a free-energy release) from their elements. However, the positive G_f^0 for nitrous oxide (N_2O) (Table 3.3) indicates that this compound does not form spontaneously. Instead, over time it decomposes spontaneously to yield N_2 and O_2 . The compounds listed in Table 3.3 are only a small subset of free energy of formation values available from physical chemistry reference sources.

Using free energies of formation, it is possible to calculate $\Delta G^{0'}$ of a reaction. For the reaction $A + B \rightleftharpoons C + D$, $\Delta G^{0'}$ is calculated by subtracting the sum of the free energies of formation of the reactants ($A + B$) from that of the products ($C + D$). Thus

$$\Delta G^{0'} = G_f^0[C + D] - G_f^0[A + B]$$

The value obtained for $\Delta G^{0'}$ tells us whether the reaction is exergonic (and can be a potential energy source for the cell) or endergonic (and requires an energy input to proceed). The phrase “products minus reactants” is a simple way to recall how to calculate changes in free energy during chemical reactions. This is illustrated for an example reaction, the oxidation of acetate to CO_2 , in Table 3.2, equation 2.

^aValues for free energy of formation taken from Speight, J. 2005. *Lange's Handbook of Chemistry*, 16th edition, and Thauer, R.K., K. Jungermann, and H. Decker. 1977. Energy conservation in anaerobic chemotrophic bacteria. *Bacteriol. Rev.* 41: 100–180.

Before free-energy calculations can be made, it is first necessary to balance the reaction. That is, (1) the total number of each kind of atom and ionic charges must be identical on both sides of the reaction, and (2) the oxidation–reduction state must balance such that all of the electrons removed from one substance are transferred to another substance. Once a reaction is balanced, its $\Delta G^{0'}$ can be calculated, and from this, the potential of the reaction as a means of energy conservation for a cell can be assessed.

Calculating Free-Energy Change in Natural Conditions

Although calculations of $\Delta G^{0'}$ are often very accurate estimates of actual free-energy changes, in some cases they are not. Consider the oxidation of propionate to H_2 and CO_2 (Figure 3.7). This reaction is important in wetlands because microorganisms called *methanogens* in these habitats ultimately consume H_2 and CO_2 and turn them into methane (CH_4), a powerful greenhouse gas (Chapters 14, 17, and 21). Propionate oxidation is quite unfavorable at standard conditions when reactants and products are all present at molar concentration ($\Delta G^{0'} = +304 \text{ kJ/mol}$). In wetlands, however, methanogens consume H_2 , lowering its concentration dramatically, and low H_2 concentrations allow propionate oxidation to become exergonic (Figure 3.7). We will see when we pick up the bioenergetics theme again in Chapter 14 that the actual concentrations of products and reactants are almost never present at molar concentrations in a microbe's natural habitat. Hence, the calculation of $\Delta G^{0'}$, while a useful approximation, can misrepresent the actual energy available to cells as they occur in the environment. In this regard, what is most relevant to a bioenergetic calculation is not $\Delta G^{0'}$, but ΔG , the

free-energy change that occurs *under the actual conditions* in which the organism is growing. The equation for ΔG takes into account the actual concentrations of reactants and products in the organism's habitat and is expressed as

$$\Delta G = \Delta G^{0'} + RT \ln K_{\text{eq}}$$

where R and T are physical constants and K_{eq} is the equilibrium constant for the reaction. For the reaction $aA + bB \rightleftharpoons cC + dD$, $K_{\text{eq}} = [\text{C}]^c[\text{D}]^d/[\text{A}]^a[\text{B}]^b$, A and B are reactants and C and D are products; a , b , c , and d are the number of molecules of each, and the brackets indicate concentrations.

Returning to the example of propionate oxidation (Figure 3.7), we can see that the reaction becomes increasingly exergonic when propionate (the reactant) increases in concentration and when H_2 (the product) decreases in concentration. Hence, propionate oxidation to CO_2 and H_2 , though unfavorable at standard conditions, becomes more favorable as reactant concentrations go up and as product concentrations go down. The H_2 concentration has a greater effect on ΔG than the propionate concentration because 7 H_2 are formed for every propionate molecule oxidized, and hence H_2 has a far greater impact on the value of the equilibrium constant for the reaction. While propionate oxidation is endergonic under standard conditions, propionate-oxidizing microbes can thrive in the environment as long as H_2 -consuming microbes (such as methanogens) coexist with them. Such interdependency is common in the microbial world and we will learn more about metabolic interactions between microbial partners in Chapter 14.

While $\Delta G^{0'}$ and ΔG are rarely identical, at this point in our understanding of bioenergetics the expression $\Delta G^{0'}$ is sufficient to appreciate the general principles of energy flow in microbial systems. The main point to keep in mind is that *only exergonic reactions* yield energy that can be conserved by the cell, and this will be our focus in the next few sections.

Figure 3.7 Calculating free energy under natural conditions (ΔG). The example is the oxidation of propionate to H_2 and CO_2 (as shown at the top of the figure, with CO_2 written as HCO_3^- [bicarbonate] because this is the form in which it naturally occurs in solution at neutral pH). This reaction is endergonic under standard conditions ($\Delta G^{0'} = +304 \text{ kJ/mol}$) but can be exergonic under natural conditions in an environment where the H_2 produced in the reaction is quickly consumed by other microbes. The ΔG was calculated at different concentrations of reactants (propionate) and products (H_2).

3.4 Cellular Energy Conservation

Chemotrophs conserve energy from chemical reactions while phototrophs conserve energy from light. We have just reviewed how to calculate the free-energy change of chemical reactions. Now we introduce mechanisms of energy conservation. Ultimately, cells conserve energy by synthesizing energy-rich compounds. We begin by reviewing the energy-rich compounds that cells commonly use to conserve energy.

Adenosine Triphosphate

The most important energy-rich phosphate compound in cells is **adenosine triphosphate (ATP)**. ATP consists of the ribonucleoside

Figure 3.8 Energy-rich bonds in compounds that conserve energy in microbial metabolism. The range in free energy of hydrolysis values for the phosphate or sulfur bonds highlighted in the compounds is listed in the table. The “R” group of acetyl-CoA is a 3'-phospho ADP group.

adenosine to which three phosphate molecules are bonded in series. From the structure of ATP (Figure 3.8), it can be seen that only two of the phosphate bonds ($\text{ATP} \rightleftharpoons \text{ADP} + \text{P}_i$ and $\text{ADP} \rightleftharpoons \text{AMP} + \text{P}_i$) have free energies of hydrolysis more exergonic than -30 kJ/mol. By contrast, the phosphate bond in AMP contains only about half as much energy as those in ADP or ATP (Figure 3.8).

Although the energy released in ATP hydrolysis is -31.8 kJ/mol, a caveat must be mentioned here to more precisely state the energy requirements for the synthesis of ATP. In an actively growing *Escherichia coli* cell, the ratio of ATP to ADP is maintained at about 7:1, and this increases the actual free-energy requirements for ATP synthesis. Thus, in an actively growing cell, the actual energy that must be released (that is, the ΔG , Section 3.3) to drive the synthesis of ATP is closer to -55 to -60 kJ/mol. Nevertheless, for the purposes of learning and applying the basic principles of bioenergetics, we will assume that reactions conform to “standard conditions” ($\Delta G^{\circ'}$), and therefore we will assume that the energy needed to drive ATP synthesis (from $\text{ADP} + \text{P}_i$) is -31.8 kJ/mol. This unit is the fundamental currency of energy conservation within the cell and we will see that a major goal of energy conservation in catabolism is to obtain sufficient energy to form ATP.

Energy-Rich Compounds

ATP is not the only energy-rich compound in the cell; several others exist that, like ATP, have energy-rich phosphate bonds, and still others have energy-rich sulfur bonds. The biosynthesis of these compounds functions to trap free energy, and their hydrolysis releases this energy to drive endergonic reactions such as ATP synthesis.

A range of molecules have bonds consisting of a phosphate linked to an organic compound (Figure 3.8). However, not all phosphate bonds are energy-rich bonds. As seen in this figure, the $\Delta G^{\circ'}$ of hydrolysis of the phosphate bond in glucose 6-phosphate is -13.8 kJ/mol. By contrast, the $\Delta G^{\circ'}$ of hydrolysis of the phosphate bond in phosphoenolpyruvate is -61.9 kJ/mol, almost four times that of glucose 6-phosphate. Although the phosphate in either compound could be hydrolyzed to release energy, cells need compounds whose $\Delta G^{\circ'}$ of phosphate hydrolysis exceeds -31.8 kJ/mol to synthesize ATP.

Some energy-rich compounds have carbon-sulfur bonds. These include, in particular, derivatives of *coenzyme A* (for example, acetyl-CoA in Figure 3.8). Coenzyme A derivatives contain energy-rich *thioester* bonds, and hydrolysis of these bonds yields sufficient free energy to couple to the synthesis of an energy-rich phosphate bond. For example, in the coupled reaction

the energy released in the hydrolysis of coenzyme A is conserved in the synthesis of ATP. We will return to the importance of coenzyme A derivatives in microbial bioenergetics many times in Chapter 14.

Mechanisms of Energy Conservation

Cells conserve energy by generating ATP through one of three fundamental mechanisms. The first mechanism is **substrate-level phosphorylation**. In substrate-level phosphorylation the energy-rich bond of a substrate is hydrolyzed to directly drive the formation of ATP. For example, hydrolysis of the phosphate bond in

phosphoenolpyruvate is sufficiently exergonic to drive ATP formation (see Figures 3.8 and 3.11). We will see that substrate-level phosphorylation is the dominant mechanism of energy conservation in fermentative organisms (see Section 3.7 and Figure 3.21).

The second mechanism of energy conservation is **oxidative phosphorylation**. In oxidative phosphorylation the movement of electrons from an electron donor to an electron acceptor (Figure 3.1b) generates a *proton motive force*. The **proton motive force** is an electrochemical gradient formed by energy-conserving reactions that transport protons outside the cytoplasmic membrane. This electrochemical gradient creates a force that is ultimately used to synthesize ATP (◀ Section 2.1 and Figure 2.4). Oxidative phosphorylation is the defining feature of respiration reactions and it is performed by diverse chemotrophic organisms (Sections 3.9–3.11).

The third mechanism of energy conservation is **photophosphorylation**. In photophosphorylation light energy is used to form the proton motive force that powers ATP synthesis and is the dominant mechanism of energy conservation in phototrophic organisms. Both photophosphorylation and oxidative phosphorylation ultimately rely on electron transfer reactions to drive the formation of the proton motive force (Section 3.11).

We now turn our attention to enzymes—the cell's premier catalysts—and the importance of catalysis in cellular metabolism.

Check Your Understanding

- What are the three fundamental mechanisms of conserving cellular energy and in what types of organisms would these mechanisms be most important?
- Explain whether 1,3-bisphosphoglycerate or glucose 6-phosphate (Figure 3.8) could be used to generate ATP through substrate-level phosphorylation.
- Which mechanisms of energy conservation rely on the proton motive force?

3.5 Catalysis and Enzymes

Free-energy calculations reveal only whether energy is released or required in a given reaction; they say nothing about the *rate* of the reaction. If the rate of a reaction is very slow, it may be of no value to a cell. For example, consider the formation of water from O_2 and H_2 . The energetics of this reaction are quite favorable: $H_2 + \frac{1}{2}O_2 \rightarrow H_2O$, $\Delta G^{0'} = -237$ kJ. However, if O_2 and H_2 were mixed in a sealed bottle, no measurable amount of water would form, even after years. This is because the bonding of O_2 and H_2 to form H_2O requires that these two gases become reactive. This requires that their bonds be broken, which requires a small amount of energy. This energy is called **activation energy**.

Activation energy can be viewed as the minimum energy required for a chemical reaction to begin. For an exergonic reaction, the situation is as shown in Figure 3.9. Although the activation energy barrier is virtually insurmountable in the absence of a *catalyst*—a substance that facilitates a reaction but is not consumed by it—in the presence of a proper catalyst, this barrier is reduced, allowing the reaction to proceed.

Figure 3.9 Activation energy and catalysis. Even chemical reactions that release energy may not proceed spontaneously if not activated. Once the reactants are activated, the reaction proceeds spontaneously. Catalysts such as enzymes lower the required activation energy.

Enzymes

Catalysts function by lowering the activation energy of a reaction (Figure 3.9), thereby increasing the reaction rate. Catalysts have no effect on the energetics or the equilibrium of a reaction but only affect the *rate* at which a reaction proceeds. Most cellular reactions will not proceed at significant rates without catalysis.

The major catalysts in cells are **enzymes**, which are proteins (or in a few cases, RNAs) that are highly specific for the reactions they catalyze. This specificity is a function of the precise three-dimensional structure of the enzyme. In an enzyme-catalyzed reaction, the enzyme combines with the reactant, called a *substrate*, forming an *enzyme–substrate complex*. Then, as the reaction proceeds, the *product* is released and the enzyme is returned to its original state, ready to catalyze a new round of the reaction (Figure 3.10). The enzyme is generally much larger than the substrate(s), and the portion of the enzyme to which substrate binds is the enzyme's *active site*; the entire enzymatic reaction, from substrate binding to product release, may take only a few milliseconds.

Many enzymes contain small nonprotein molecules that participate in catalysis but are not themselves substrates. These small molecules can be divided into two classes based on the way they associate with the enzyme: *prosthetic groups* and *coenzymes*. Prosthetic groups bind tightly to their enzymes, usually covalently and permanently. The heme group present in cytochromes such as cytochrome *c* (Section 3.8) is an example of a prosthetic group. By contrast, **coenzymes**, with a few exceptions, are loosely and often transiently bound to enzymes; thus, a single coenzyme molecule may associate with a number of different enzymes. NADH is an example of a coenzyme (Figures 3.5 and 3.6), as is ATP. Most coenzymes are derivatives of vitamins (▶ Section 4.1 and Table 4.1).

Enzyme Catalysis

To catalyze a reaction, an enzyme must bind its substrate and position it properly in its active site. The enzyme–substrate complex

cycle of an
enzyme

Figure 3.10 The catalytic cycle of an enzyme. The enzyme depicted here, lysozyme, catalyzes the cleavage of the β -1,4-glycosidic bond in the polysaccharide backbone of peptidoglycan (◀ Section 2.3). Following substrate binding in the enzyme's active site, strain is placed on the bond, and this favors breakage. Space-filling model of lysozyme courtesy of Richard Feldmann.

(Figure 3.10) aligns reactive groups in the substrate(s) and places strain on specific bonds. This reduces the activation energy required to make the reaction proceed (Figure 3.9). This is shown in Figure 3.10 for the enzyme lysozyme, an enzyme whose substrate is the polysaccharide backbone of peptidoglycan, the bacterial cell wall polymer (◀ Section 2.3).

The reaction depicted in Figure 3.9 is exergonic. By contrast, some enzymes catalyze endergonic reactions where they convert energy-poor substrates into energy-rich products. In these cases not only must an activation energy barrier (Figure 3.9) be overcome, but sufficient free energy must also be put into the reaction in order to raise the energy level of the substrates to that of the products. This is done by *coupling* the energy-requiring reaction to an energy-yielding one, such as the hydrolysis of ATP or dissipation of the proton motive force, so that the overall reaction proceeds with a free-energy change that is either negative in arithmetic sign or zero.

Theoretically, all enzymes are reversible in their activity. However, enzymes that catalyze highly exergonic or highly endergonic reactions typically function in only one direction. If a particularly exergonic or endergonic reaction needs to be reversed, a different enzyme usually catalyzes the reverse reaction.

- What is activation energy?

II • Catabolism: Chemoorganotrophs

Chemoorganotrophs use organic carbon molecules to fuel metabolism, and glycolysis and the citric acid cycle are central metabolic pathways used in the metabolism of organic carbon molecules.

We have learned in the previous sections that cells harvest energy from redox reactions and they conserve this energy in the synthesis of ATP and other high-energy compounds. We have also learned that there are many different metabolic types of organisms, each defined by its source of energy (Figure 3.3).

Here we examine the metabolic pathways that cells use to transfer electrons and conserve energy. We begin by examining chemoorganotrophs that perform fermentation and respiration. **Fermentation** is a form of anaerobic catabolism in which organic compounds both donate electrons and accept electrons, and redox balance is achieved without the need for external electron acceptors. By contrast, **respiration** is a form of aerobic or anaerobic catabolism in which an electron donor, which can be either organic or inorganic, is oxidized using an external electron acceptor such as O_2 (in aerobic respiration) or some other compound (in anaerobic respiration). We will revisit the concepts of fermentation and respiration in detail in Chapter 14 and so focus here only on the essentials that define these processes.

3.6 Glycolysis, the Citric Acid Cycle, and the Glyoxylate Cycle

Chemoorganotrophs obtain the electrons they need to conserve energy from the oxidation of organic compounds, such as glucose. A nearly universal pathway for the catabolism of glucose is the *Embden–Meyerhof–Parnas* pathway, better known as **glycolysis**, a series of reactions in which glucose is oxidized to pyruvate. Many metabolic reactions are modular and glycolysis is a prime example of such a module. Glycolysis can participate in several forms of catabolism including fermentation, aerobic respiration, and anaerobic respiration.

Glycolysis

Mastering
Microbiology
Animation:
Glycolysis:
Steps

Glycolysis can be divided into two stages, each consisting of one or more enzymatic reactions. Stage I consists of “preparatory” reactions; these are not redox reactions and do not release energy but instead form a key intermediate of the pathway. In stage II, redox reactions occur, energy is conserved, and two molecules of pyruvate are formed (**Figure 3.11**).

To begin glycolysis, glucose is phosphorylated to form glucose 6-phosphate. The latter is then isomerized to fructose 6-phosphate, and a second phosphorylation leads to the production of fructose 1,6-bisphosphate. These steps consume, rather than produce, ATP. The enzyme aldolase then splits fructose 1,6-bisphosphate into two

3-carbon molecules, *glyceraldehyde 3-phosphate* and its isomer, *dihydroxyacetone phosphate*, which is converted into glyceraldehyde 3-phosphate. To this point, all of the reactions, including the consumption of ATP, have proceeded without any redox changes (**Figure 3.11**).

The first redox reaction of glycolysis occurs when glyceraldehyde 3-phosphate is oxidized to 1,3-bisphosphoglycerate. In this reaction (which occurs twice, once for each of the two glyceraldehyde 3-phosphates), the enzyme glyceraldehyde-3-phosphate dehydrogenase reduces NAD^+ to NADH. Simultaneously, each glyceraldehyde 3-phosphate molecule is phosphorylated by the addition of a molecule of inorganic phosphate. This reaction, in which *inorganic* phosphate is converted to *organic* form, sets the stage for energy conservation, since 1,3-bisphosphoglycerate is an energy-rich compound (**Figure 3.11**; see also **Figure 3.8**). ATP is then synthesized by substrate-level phosphorylation when (1) each molecule of 1,3-bisphosphoglycerate is converted to 3-phosphoglycerate, and (2) each molecule of phosphoenolpyruvate is converted to pyruvate (**Figure 3.11**). As a result, glycolysis consumes *two* ATP molecules in stage I and produces *four* ATP molecules in stage II. The result is that glycolysis produces *a net yield of 2 molecules of ATP, 2 molecules of NADH, and 2 molecules of pyruvate per molecule of glucose*.

The glycolytic pathway on its own, while sufficient to make ATP, is insufficient to sustain life because it lacks redox balance. That is, glycolysis produces NADH but it lacks an electron acceptor and so

Figure 3.11 Embden–Meyerhof–Parnas pathway (glycolysis). The sequence of reactions in the catabolism of glucose to pyruvate. Glycolysis results in the formation of 2 each of pyruvate, ATP, and NADH per glucose molecule.

lacks the ability to regenerate the NAD^+ needed to oxidize glyceraldehyde-3-P to 1,3-bisphosphoglycerate. Cells performing glycolysis can achieve redox balance by using one of several different mechanisms including fermentation, where NADH oxidation is linked to the reduction of pyruvate (Section 3.7), or respiration, where glycolysis is coupled to the citric acid cycle and respiration (Section 3.8).

The Citric Acid Cycle

The pathway by which pyruvate is oxidized to CO_2 is called the **citric acid cycle (CAC)** (Figure 3.12). Pyruvate from glycolysis is decarboxylated, leading to the production of CO_2 , NADH , and the energy-rich compound *acetyl-CoA*, which enters the CAC (Figure 3.12 and see Figure 3.8). The acetyl group of acetyl-CoA combines with the four-carbon CAC intermediate oxaloacetate, forming the six-carbon compound citric acid, for which the CAC is named.

A sequence of reactions follows, and two additional CO_2 molecules, three more NADH , and one FADH_2 are formed per pyruvate oxidized. Ultimately, oxaloacetate is regenerated as the next acetyl acceptor, thus completing the cycle (Figure 3.12). The result is that the citric acid cycle produces a *net yield of 1 molecule of ATP (or GTP), 4 molecules of NADH (or NADPH), 1 molecule of FADH_2 , and 3 molecules of CO_2 per molecule of pyruvate.*

Linkage of glycolysis with the citric acid cycle allows one molecule of glucose to be completely oxidized to six molecules of CO_2 , while producing 4 molecules of ATP (2 in glycolysis and 2 in the CAC). However, redox is still out of balance because these pathways have combined to produce 10 molecules of NADH and 2 of FADH_2 per molecule of glucose. Redox balance is ultimately achieved in respiration reactions (Section 3.9). However, before we turn our attention to respiration, we consider another important aspect of the citric acid cycle.

Mastering
Microbiology
Animation:
Kreb's Cycle:
Steps

Figure 3.12 The citric acid cycle. The citric acid cycle begins when the two-carbon compound acetyl-CoA (derived from pyruvate) condenses with the four-carbon compound oxaloacetate to form the six-carbon compound citrate. Through a series of oxidations and transformations, citrate is converted to two CO_2 and the acetyl acceptor molecule, oxaloacetate. For every pyruvate that enters the cycle, 3 CO_2 , 1 ATP, 4 NADH , and 1 FADH_2 are produced.

Biosynthesis and the Citric Acid Cycle

Besides its role in oxidizing pyruvate to CO_2 , the citric acid cycle also plays a major role in biosynthesis. The cycle is composed of several key organic compounds, small amounts of which are drawn off during growth to produce new cell material. Particularly important in this regard are α -ketoglutarate and oxaloacetate, which are precursors of several amino acids (Section 3.14), and succinyl-CoA, needed to form cytochromes, chlorophyll, and related molecules. Any shortage of oxaloacetate is corrected by the addition of CO_2 (carboxylation) to pyruvate or phosphoenolpyruvate (Figure 3.12).

Oxaloacetate is also an important intermediate because it can be converted to phosphoenolpyruvate (a precursor of glucose) if necessary (Section 3.13). In addition, acetate is important because it provides the raw material for fatty acid biosynthesis (Section 3.15). The CAC thus plays two major roles in the cell: *oxidation of organic compounds* and *the biosynthesis of key metabolites*. The same can be said about the glycolytic pathway, as certain intermediates from this pathway are also drawn off for biosynthetic needs (Sections 3.13 and 3.14) and then replenished from glucose in the next round of glycolysis.

Other Pathways for Chemoorganotrophy

Chemoorganotrophs can use glycolysis and the CAC to oxidize several compounds including glucose, citrate, malate, fumarate, and succinate (all C_4 or C_6 compounds). In addition, many unrelated catabolic pathways can be linked to glycolysis and the CAC to enable the oxidation of an even wider diversity of organic compounds. For example, many sugars can be converted to glucose by *isomerase* enzymes and then metabolized by glycolysis. Likewise, isomerases that yield CAC intermediates can be used to metabolize a wide range of organic compounds.

Some chemoorganotrophs can also grow on two-carbon (C_2) compounds by using the **glyoxylate cycle** (Figure 3.13). Microbes cannot grow on C_2 compounds such as acetate by using the CAC only. This is because some oxaloacetate must be drawn off from the CAC to biosynthesize glucose and amino acid precursors (Sections 3.13 and 3.14). It is possible to readily synthesize oxaloacetate from a range of C_4 and C_6 compounds but not from C_2 compounds. This inability to regenerate oxaloacetate during growth on acetate means that the CAC would starve for the oxaloacetate needed to accept the acetyl group from acetyl-CoA (Figure 3.12). Hence, cells use the glyoxylate cycle (so named because the C_2 compound *glyoxylate* is a key intermediate) to grow using C_2 compounds.

The glyoxylate cycle is composed of several citric acid cycle enzymatic reactions plus two additional enzymes: *isocitrate lyase*, which cleaves isocitrate into succinate and glyoxylate, and *malate synthase*, which converts glyoxylate and acetyl-CoA to malate (Figure 3.13). The succinate formed can be used for biosynthesis, while the glyoxylate combines with acetyl-CoA (C_2) to yield malate (C_4). From malate, the acceptor molecule oxaloacetate is produced and can enter a new round of acetyl-CoA oxidation in the citric acid cycle (Figure 3.13).

Another example of this principle comes from chemoorganotrophs that grow on C_3 compounds. Cells using standard CAC reactions to grow on C_3 compounds, such as pyruvate, are also unable to regenerate oxaloacetate. However, carboxylation reactions catalyzed by the enzymes *pyruvate carboxylase* or *phosphoenolpyruvate*

Figure 3.13 The glyoxylate cycle. These reactions occur in conjunction with the citric acid cycle when cells grow on two-carbon electron donors, such as acetate. The glyoxylate cycle regenerates oxaloacetate (from malate) to maintain an acetyl acceptor for the citric acid cycle.

carboxylase, which convert pyruvate or phosphoenolpyruvate into oxaloacetate (respectively), allow cells growing on C_3 compounds to regenerate oxaloacetate (Figure 3.12).

It should thus be clear that metabolic reactions are modular entities and that the reactions of glycolysis, the citric acid cycle, and the glyoxylate cycle allow for a wide diversity of organic electron donors to fuel the energy needs of chemoorganotrophs.

Check Your Understanding

- Which reactions in glycolysis are redox reactions?
- Why does an organism need the enzyme *pyruvate carboxylase* to enable growth if pyruvate is its sole source of energy and reducing power?
- Why is it not possible for an organism to grow by using only glycolysis?

3.7 Principles of Fermentation

Microbes that ferment glucose achieve energy conservation by substrate-level phosphorylation and achieve redox balance by reducing the pyruvate produced in glycolysis (Section 3.6) and then excreting the reduced molecule to the environment as a waste product (Figure 3.14). These fermentation products are often highly reduced substances such as organic acids or alcohols. However,

Figure 3.14 The essentials of fermentation. An organic compound is oxidized, and the electrons are ultimately recycled back to one of the oxidized organic products because an external electron acceptor is lacking. The fermentation product so formed is excreted from the cell and ATP is produced by substrate-level phosphorylation. Most of the fermentable substrate is used for energy generation and only a relatively small amount is used for biosynthesis.

fermentation products are not waste products to humans. Instead, they are the foundation of the baking and fermented beverage industries, including beer and wine production, and are key ingredients in many other fermented foods, such as the lactic and other acids in fermented dairy products (yogurt, sour cream, buttermilk, and the like), cheeses, pickles, and certain sausages and fish products (◀ Section 1.6). In addition, fermentation products produced by the human microbiome can exert a powerful influence on human health (Chapter 24).

Energy Conservation and Redox Balance in Fermentation

There are a tremendous diversity of fermentation reactions and many employ glycolysis, but in the final analysis, all fermentations must achieve two major results: first, the cell must conserve energy, and second, the cell must achieve a final redox balance. Since fermentative organisms rely on substrate-level phosphorylation to conserve energy, they need to produce compounds that contain energy-rich bonds with which to synthesize ATP (Section 3.4). In addition, since fermentative organisms lack an external electron acceptor they need to find a way to oxidize NADH back to NAD⁺. Fermentative organisms solve the latter problem by creating an electron acceptor from the organic electron donor they consumed. For example, yeast ferments one molecule of glucose to two molecules of ethanol and two molecules of CO₂. During this fermentation, yeast gets all of its ATP from glycolysis and then replenishes NAD⁺ by donating electrons from NADH to pyruvate, which is the end product of glycolysis (Figure 3.11). In this way, pyruvate is the electron acceptor, and the reduction of pyruvate produces the fermentation products ethanol and CO₂, which are excreted from the cell.

Lactic acid bacteria provide an alternative example of this same principle. These bacteria convert one molecule of glucose to two molecules of lactic acid (see Figure 3.21). Like yeast, lactic acid bacteria produce all of their ATP in glycolysis and achieve redox balance by reducing pyruvate. However, unlike yeast, lactic acid bacteria

employ different enzymes to reduce pyruvate and as a result, produce lactic acid as their fermentation product instead of ethanol plus CO₂. Lactic acid bacteria are a tremendously important group of microorganisms. They are responsible for the production of many important fermented foods (◀ Figure 1.16). Lactic acid bacteria are also the cause of dental caries, and the lactic acid they produce is essential to maintaining the health of the human large intestine and vagina (Chapter 24).

Fermentative Diversity

While sugars can be readily fermented using glycolytic reactions, there is a tremendous diversity of fermentative pathways. Many different organic substrates can be fermented, including amino acids, fatty acids, purines, pyrimidines, and even aromatic compounds. Many fermentative organisms that use these substrates produce acetate or other volatile fatty acids (for example, propionate, butyrate) as fermentation products. Volatile fatty acid fermentation products contribute to energy conservation because they provide an opportunity to make ATP by substrate-level phosphorylation. The key intermediate in such reactions is the coenzyme-A derivative of each fatty acid, since these are energy-rich compounds. For example, the final step of the butyric acid fermentation performed by the anaerobic bacterium *Clostridium butyricum* is

The formation of butyryl-CoA, which has an energy-rich bond, allows *C. butyricum* to make ATP by substrate-level phosphorylation. In addition, redox balance in many fermentative organisms can be improved by the production of molecular hydrogen (H₂). The 2 H⁺/H₂ redox couple has a very low reduction potential ($\Delta E_0' = -0.42$) and so only organisms that produce very low reduction potentials in their metabolisms can produce H₂ (for example, NADH cannot reduce H⁺ to H₂, Figure 3.4). Often the production of H₂ is associated with the activity of *ferredoxin*, a very low-potential electron carrier (Section 3.8) and catalyzed by the enzyme *hydrogenase*.

Fermentation reactions support the growth of an enormous diversity of microorganisms, but substrate-level phosphorylation can only conserve a fraction of the energy available in organic substrates. We will see in the next two sections that respiration can conserve far more energy than fermentation and is the favored form of metabolism in oxic environments.

Check Your Understanding

- Why do lactic acid bacteria produce lactic acid?
- Why is acetate formation energetically beneficial during fermentative metabolism?
- What two metabolic events result from any fermentation?

3.8 Principles of Respiration: Electron Carriers

In *respiration*, electrons are transferred from reduced electron donors such as glucose to external electron acceptors such as O₂. During glycolysis and the citric acid cycle, the complete oxidation of glucose

to 6 CO₂ produces a considerable amount of NADH and FADH₂ (Figure 3.12). These molecules must be reoxidized back to NAD⁺ and FAD in order to achieve redox balance. In glucose respiration, NADH and FADH₂ are reoxidized when they donate electrons to electron transport reactions. *Electron transport* takes place within the cytoplasmic membrane, culminating in the reduction of an external electron acceptor and the formation of an electrochemical gradient across the membrane. The electrochemical gradient is formed when protons (or in some cases, other ions) are pumped across the cytoplasmic membrane, and this electrochemical gradient—the proton motive force—is ultimately used to conserve energy through ATP synthesis. Hence, at a fundamental level, respiration is a process in which chemical energy from redox reactions is conserved by using electron transport reactions to pump protons (or other ions) across a membrane. We now focus on the enzymes, cofactors, and coenzymes that participate in electron transfer reactions.

NADH Dehydrogenases and Flavoproteins

Electron transport reactions occur within membranes, typically in the cytoplasmic membrane of prokaryotic cells or the mitochondrial membrane of eukaryotic cells. Several types of oxidation–reduction enzymes participate in electron transport. These include *NADH dehydrogenases*, *flavoproteins*, *iron–sulfur proteins*, and *cytochromes*. Also participating are small nonprotein electron carriers called *quinones*. The carriers are arranged in the membrane in order of *increasingly more positive* reduction potential, with NADH dehydrogenase first and the cytochromes last (see Figures 3.16 and 3.19).

NADH dehydrogenases contain an active site that binds NADH. The 2 e[−] and the H⁺ from NADH, and one H⁺ from the cytoplasm, are transferred by the NADH dehydrogenase to a flavoprotein, the next carrier in the chain. This regenerates NAD⁺, which can return to participate in glycolysis, the citric acid cycle, or other cellular processes (Sections 3.6 and 3.7). Flavoproteins contain a derivative of the vitamin riboflavin (Figure 3.15). The flavin portion, which is bound to its protein as a prosthetic group, is reduced as it accepts 2 e[−] + 2 H⁺ and oxidized when 2 e[−] are passed to the next carrier in the chain (note that flavoproteins *accept* 2 e[−] + 2 H⁺ but *donate* only electrons, the protons are ultimately released to the cytoplasm). Two types of flavins are commonly found in cells, flavin mononucleotide (FMN, Figure 3.15) and flavin adenine dinucleotide (FAD).

Cytochromes, Other Iron Proteins, and Quinones

Cytochromes are proteins that contain heme prosthetic groups (Figure 3.16). Cytochromes undergo oxidation and reduction through loss or gain of an electron by the iron atom that exists as either Fe²⁺ or Fe³⁺. Several classes of cytochromes exist, differing widely in their reduction potentials (Figure 3.4). Different classes of cytochromes are designated by letters, such as cytochrome *a*, cytochrome *b*, cytochrome *c*, and so on, depending on the type of heme they contain. The redox potential of a cytochrome is ultimately governed by its

Figure 3.15 Flavin mononucleotide (FMN), a hydrogen atom carrier. The site of oxidation–reduction (dashed red circle) is the same in FMN and the related coenzyme flavin adenine dinucleotide (FAD, not shown). FAD contains an adenosine monophosphate (AMP) group bonded through the phosphate group on FMN.

protein structure and the type of heme present. Occasionally, cytochromes form into complexes with other cytochromes or with iron–sulfur proteins. An important example is the cytochrome *bc*₁ complex, which is a multiprotein enzyme complex that contains two different *b*-type cytochromes and one *c*-type cytochrome. The cytochrome *bc*₁ complex plays an important role in energy metabolism, as we will see in the next section.

In addition to the cytochromes, in which iron is bound to heme, one or more proteins with nonheme iron are also components of electron transport chains. These proteins contain prosthetic groups made up of clusters of iron and sulfur atoms, with Fe₂S₂ and Fe₄S₄ clusters being the most common (Figure 3.17). For example, bacterial **ferredoxin**, a nonheme iron–sulfur protein of low reduction potential (about -0.4 V) (Table 3.1) and an important component in H₂ production (Section 3.7), contains an Fe₄S₄ cluster. The reduction potentials of iron–sulfur proteins vary from -0.2 to about -0.45 V ,

Figure 3.16 Cytochrome and its structure. (a) Structure of heme, the iron-containing portion of cytochromes. Hemes are tetrapyrroles, composed of four pyrrole rings. Cytochromes carry electrons only, and the redox site is the iron atom, which can alternate between the Fe²⁺ and Fe³⁺ oxidation states. (b) Space-filling model of cytochrome *c*; heme (light blue) is covalently linked via disulfide bridges to cysteine residues in the protein (dark blue).

Figure 3.17 Arrangement of the iron-sulfur centers of nonheme iron-sulfur proteins. (a) Fe_2S_2 center. (b) Fe_4S_4 center. The cysteines (Cys) link the protein to its Fe/S cluster.

depending on the iron-sulfur cluster present, the structure of the protein that contains it, and how the cluster is embedded in the protein. Thus, different iron-sulfur proteins can function at different locations in the electron transport chain. Like cytochromes, iron-sulfur proteins carry only electrons.

Quinones (**Figure 3.18**) are small hydrophobic redox molecules that lack a protein component. Because they are small and hydrophobic, quinones can move about within the membrane. Like the flavins (Figure 3.15), quinones accept $2e^- + 2H^+$ but transfer only $2e^-$ to the next carrier in the chain. Quinones typically function to link iron-sulfur proteins (Figure 3.17) and the initial cytochrome (Figure 3.16) in the electron transport chain. Several types of quinones exist, but ubiquinone (also called coenzyme Q) and menaquinone are the most common quinones and are widely distributed in species of *Bacteria* and *Archaea*.

Check Your Understanding

- In what major way do quinones differ from other electron carriers in the membrane?
- Which electron carriers described in this section accept $2e^- + 2H^+$? Which accept electrons only?
- Consider an electron transport chain that transports electrons from NADH to O_2 . In what order would cytochromes *a*, *b*, and *c* need to occur in the electron transport chain? (*Hint*: Refer to Figure 3.4.)

3.9 Principles of Respiration: Generating a Proton Motive Force

As we will see later (Section 3.10), respiration can be either aerobic or anaerobic. However, energy conservation in all forms of respiration is linked to an energized state of the membrane—the proton motive force. In addition, we will see that electron transfer reactions and the generation of a proton motive force are also required for energy conservation in phototrophy (Section 3.11). Hence, electron transport and the generation of a proton motive force is a unifying concept that underlies energy conservation in all forms of metabolism except fermentation.

Electron Transport

Understanding the linkage between electron transport and ATP synthesis requires an appreciation for the organization of the electron transport chain in the cytoplasmic membrane (**Figure 3.19**). While

Figure 3.18 Structure of oxidized and reduced forms of ubiquinone (coenzyme Q, or CoQ). The five-carbon unit in the side chain (an isoprenoid) occurs in multiples, typically 6–10. Oxidized ubiquinone requires $2e^-$ and $2H^+$ to become fully reduced (dashed red outline).

the exact composition of the electron transport chain varies between organisms, and multiple electron transport chains can sometimes function simultaneously in a single organism, the principles of electron transport are nearly universal.

Electron transport begins when an electron donor adds electrons to the electron transport chain. In chemoorganotrophic organisms, electrons enter electron transport from either NADH or FADH_2 . By contrast, many different inorganic electron donors can feed into electron transport in various chemolithotrophic organisms (see Section 3.11). However, regardless of the source of electrons, electron carriers within the transport chain are embedded in the membrane in order of their *increasingly positive* reduction potentials (Figure 3.19; see also Figure 3.4). During electron transport, electrons are passed on from lower-potential (more negative $\Delta E_0'$) carriers to higher-potential (more positive $\Delta E_0'$) carriers until at the end of the chain they ultimately reduce a *terminal electron acceptor*, such as O_2 .

The movements of electrons through the electron transport chain are exergonic reactions that provide the free energy to pump protons to the *outer surface* of the membrane, thereby generating the proton motive force. Recall that H_2O naturally dissociates to form H^+ and OH^- . Hence, removal of H^+ from the cytoplasm results in the accumulation of OH^- on the cytoplasmic side of the membrane. Though small, H^+ are not free to diffuse across the membrane because they are charged and polar; thus, they must be extruded and this occurs during electron transport reactions. This separation of H^+ from OH^- creates a difference in pH and an electrochemical potential across the membrane, and this electrochemical potential energizes the membrane (Figure 3.19) much like the potential energy that exists from charge separation in a battery. This electrochemical gradient establishes the proton motive force, which can be used by the cell to do work in the form of ATP synthesis, active transport, motility, and a few other energy-requiring reactions.

The mechanisms of electron transport in a model chemoorganotrophic bacterium widely used for studies of respiration, *Paracoccus denitrificans*, is shown in Figure 3.19. This bacterium can grow by aerobic respiration of glucose. In so doing, it uses glycolysis and the citric acid cycle to produce NADH and FADH_2 destined for the electron transport chain, and it uses O_2 as its terminal electron acceptor. We know the electron transport chain of *P. denitrificans* in detail because it is used as a model system to study mitochondrial

FMN, flavin mononucleotide; FAD, flavin adenine dinucleotide; Q, quinone; Fe/S, iron-sulfur protein; cyt *a*, *b*, *c*, cytochromes (b_L and b_H , low- and high-potential *b*-type cytochromes, respectively). The Q-cycle occurs at Complex III (cytochrome bc_1). During the Q-cycle, two molecules of QH_2 are oxidized and a total of 4 H^+ exchanged across the membrane for every 2 e^- that pass through the complex. Complex II, the succinate dehydrogenase complex, bypasses Complex I and feeds electrons directly into the quinone pool at a more positive E_0' than NADH (see the redox tower in Figure 3.4).

function. This resemblance occurs because the mitochondrion is the result of an ancient symbiosis that took place between a bacterial cell and the ancestor of all *Eukarya* (► Section 13.4). Electron transport takes place in the cytoplasmic membrane of *P. denitrificans* and in the mitochondrial membrane of eukaryotic cells.

Generation of the Proton Motive Force: Complexes I and II

In *P. denitrificans* and many aerobic bacteria, electron transport begins at Complex I (Figure 3.19). The term *complex* refers to the fact that this system is composed of many proteins that function as a unit (for example, in *Escherichia coli*, Complex I contains 14 different proteins). Complex I is also called *NADH:quinone oxidoreductase* (or simply *NADH dehydrogenase*) because the overall reaction is one in which NADH is oxidized and a quinone (Figure 3.18) is reduced. Complex I oxidizes NADH to NAD^+ and transfers the resulting 2 e^- to a protein containing an FMN coenzyme and from there to a series of Fe/S proteins within the complex, before ultimately reducing ubiquinone (Q) to ubiquinol (QH_2). This reduction causes ubiquinone to pick up 2 H^+ from the inside of the cell. The QH_2 is able to diffuse within the membrane to Complex III, the next step in the electron transport chain. In addition, the electron transfer reactions within Complex I cause a conformational change within the complex resulting in transport of 4 H^+ across the membrane (Figure 3.19).

As an alternative entry point to the electron transport chain, electrons from FADH_2 enter at Complex II. Complex II is also called

the *succinate dehydrogenase complex* because the oxidation of succinate to fumarate in the citric acid cycle (Figure 3.12) reduces FAD^+ to FADH_2 , ultimately resulting in the reduction of Complex II (Figure 3.19). The 2 e^- from FADH_2 are transferred through Complex II to ubiquinone (Q), which accepts these 2 e^- and 2 H^+ from the cytoplasm to become ubiquinol (QH_2). In this way Complexes I, II, and III are all linked by the *quinone pool*. Quinones are reduced by either Complex I or Complex II, and their reduction requires 2 H^+ , which are obtained from the cytoplasmic side of the membrane; QH_2 is then free to diffuse within the membrane to Complex III. However, electrons entering at Complex I result in greater energy conservation than those entering at Complex II because the former translocates 4 additional H^+ for every 2 e^- transported (Figure 3.19).

Complexes III and IV: bc_1 and *c*- and *a*-Type Cytochromes

Complex III consists of the cytochrome bc_1 complex (Figure 3.19). Electrons enter Complex III from QH_2 at the Q_o site and they leave when donated to cytochrome *c*. When QH_2 donates its 2 e^- to Complex III, it releases its two H^+ outside of the cytoplasmic membrane, contributing to the proton motive force. However, QH_2 carries 2 e^- and cytochrome *c* only carries 1 e^- . This difference creates an opportunity for conserving additional energy through a mechanism known as the *Q-cycle*. During the Q-cycle, cytochrome bc_1 carries out an *electron bifurcation* in which the two 2 e^- from QH_2 ($E_0' = +0.09 \text{ V}$)

are sent in different directions. The first e^- is transported to cytochrome c ($E_0' = +0.25$ V) in an exergonic reaction whose free-energy release helps drive transfer of the second e^- in the slightly endergonic reaction to subunit b_L ($E_0' = -0.06$ V). The reduction potential of the b_L subunit is sufficient to transfer e^- to the b_H subunit and then ultimately back to a second molecule of ubiquinone (Q) that is docked at the Q_i site of Complex III. It takes *two* such cycles to reduce fully the ubiquinone at the Q_i site to QH_2 , and the net result of the Q-cycle is that 4 H^+ are transferred to the cytoplasmic side of the membrane for every 2 e^- that move through Complex III to cytochrome c (Figure 3.19).

Cytochrome c functions as a periplasmic shuttle to transfer e^- from Complex III to the high-redox-potential cytochromes a and a_3 of Complex IV (Figure 3.19). Complex IV functions as the terminal oxidase and reduces O_2 to 2 H_2O in the final step of the electron transport chain. It takes 4 e^- to reduce O_2 to 2 H_2O a reaction that also consumes 4 H^+ from the cytoplasm. This transfer of electrons causes a conformational change in Complex IV that allows 1 H^+ to be pumped to the outer surface of the membrane for every e^- transferred through Complex IV (Figure 3.19).

The net result for an organism like *P. denitrificans* is that for every 2 e^- transported from NADH to O_2 , a total of 10 H^+ are transferred to the outside of the membrane (4 at Complex I, 4 at Complex III, and 2 at Complex IV), and another 2 are consumed in the cytoplasm during the formation of water. In contrast, for every 2 e^- transported from $FADH_2$ to O_2 a total of 6 H^+ are transferred to the outside of the membrane (4 at Complex III and 2 at Complex IV), and another 2 are consumed in the cytoplasm during the formation of water.

Thus far in respiration we have disposed of electrons generated in various catabolic reactions and simultaneously generated a proton motive force. The latter drives ATP synthesis through the activity of a remarkable and extremely small cellular motor, and we consider this now.

ATP Synthase

How does the proton motive force (pmf), generated from electron transport, actually drive ATP synthesis? Interestingly, a strong parallel exists between the mechanism of ATP synthesis and the mechanism that drives rotation of the flagellar motor in swimming bacteria (◀ Section 2.9). A large protein complex called **ATP synthase (ATPase)** uses energy from the pmf to catalyze formation of ATP (Figure 3.20). As it does for the flagellar motor, the pmf generates torque within the ATP synthase enzyme complex, and this torque is translated into rotary motion, creating mechanical energy that is used to catalyze the chemical synthesis of ATP from ADP and P_i . ATP formation by ATP synthase is called *oxidative phosphorylation* when the pmf is generated by respiratory electron flow. In contrast, ATP formation by ATP synthase is called *photophosphorylation* when the pmf is generated from light energy during phototrophy (Section 3.11).

ATPases consist of two components, a multiprotein complex called F_1 that sticks into the cytoplasm and actually catalyzes ATP synthesis, and a membrane-integrated multiprotein complex called F_o that carries out proton translocation across the membrane (Figure 3.20). ATP synthase is found in nearly all cellular organisms, and this enzyme complex is highly conserved, indicating that it is of ancient origin and was likely present in the common ancestor of all cells (Chapter 13).

ATPase catalyzes a reversible reaction between ATP and $ADP + P_i$, and F_1 and F_o are actually two rotary motors. The movement of protons through the ATPase drives the rotation of its c protein subunits, which are organized in a ring within the F_o subunit. Each c protein subunit picks up one H^+ from outside the membrane and deposits it in the cytoplasm for every complete revolution. This generates a torque that is transmitted to F_1 via the coupled rotation of the γ subunits (Figure 3.20). The rotation causes conformational changes in the β subunits of F_1 that allows them to bind $ADP + P_i$.

Figure 3.20 Structure and function of the reversible ATP synthase (ATPase) in *Escherichia coli*.

(a) Schematic. F_1 , the stator, consists of five different polypeptides forming an $\alpha_3\beta_3\gamma\epsilon\delta$ complex. F_1 is the catalytic complex responsible for the interconversion of $ADP + P_i$ and ATP. F_o , the rotor, is integrated in the membrane and consists of three polypeptides in an ab_2c_{12} complex. As protons enter, the dissipation of the proton motive force drives ATP synthesis ($3\text{--}5 H^+/ATP$). (b) Space-filling model. The color-coding corresponds to the art in part a. Since proton translocation from outside the cell to inside the cell leads to ATP synthesis by ATPase, it follows that proton translocation from inside to outside in the electron transport chain (Figure 3.19) represents work done on the system and a source of potential energy. This energy can be used to drive a number of energy-requiring processes in the cell, including in particular motility and some forms of nutrient transport. Nearly all cells of all domains contain ATPases. Also, some bacterial and archaeal ATPases are linked to a sodium (Na^+) rather than a proton (H^+) gradient.

Siegfried Engelbrecht-Vandré

ATP is synthesized when the β subunits return to their original conformation and the free energy captured in the rotated β subunits is released. For every full rotation of the c ring within the F_0 subunit, three ATP are formed by the F_1 subunit. The ATPase of *E. coli* has 10 c protein subunits and as a result, approximately 3.3 H^+ are required to synthesize one ATP. However, the number of c protein subunits within an ATPase varies from 8 to 15 in different organisms and thus the number of protons needed to synthesize one ATP also varies.

Oxidative phosphorylation allows the cell to conserve far more energy than is possible in fermentation because the substrate, for example glucose, is completely oxidized (Figure 3.21). A total of 38 ATP are synthesized during the aerobic respiration of glucose to CO_2 , with 34 of these formed as a result of oxidative phosphorylation (Figure 3.21). By contrast, in lactic acid fermentation, only 2 ATP are produced by substrate-level phosphorylation during the oxidation of glucose in glycolysis. Lactic acid bacteria excrete lactate, which still contains considerable free energy that has not been conserved by the cell.

ATPases are reversible motors. Hence, ATP hydrolysis can reverse the activity of ATPase and cause protons to be transported out of the cytoplasm. The net result in this case is *generation of* rather than *dissipation of* the proton motive force. Reversibility of the ATPase explains why strictly fermentative bacteria still contain ATPases even though they lack electron transport chains and are unable to carry out oxidative phosphorylation. Many important reactions in the cell, such as flagellar rotation and some forms of transport, are coupled to energy from the proton motive force. Thus, in these strictly fermentative organisms, ATPase hydrolyzes ATP formed from substrate-level phosphorylation (Section 3.7) to generate the pmf needed to carry out cellular functions such as motility and transport.

Lactic acid fermentation

Aerobic respiration

Figure 3.21 Energetics in fermentation and aerobic respiration. Fermentation and respiration both oxidize NADH and allow for the regeneration of NAD^+ . However, respiration conserves far more energy than fermentation as a result of oxidative phosphorylation. Note that reduction of 6 O_2 with 24 e^- produces 12 H_2O while only 6 H_2O are produced in the net reaction. The difference between the gross and net production of water occurs because H_2O is in equilibrium with H^+ and OH^- and only the net production of water is written in the balanced reaction. SLP, substrate-level phosphorylation; Ox. Phos., oxidative phosphorylation; CAC, citric acid cycle; ET, electron transport.

III • Catabolism: Electron Transport and Metabolic Diversity

The respiration of organic or inorganic electron donors and the light-driven reactions of photosynthesis all generate ATP by harvesting energy from the proton motive force that forms from electron transport reactions in the cytoplasmic membrane.

With the exception of fermentation, in which energy is conserved by substrate-level phosphorylation (Section 3.7), all other mechanisms of energy conservation are linked to the proton motive force (or in a few organisms, a gradient of sodium ions, Na^+ , instead of protons, as we will see in Chapter 14). Whether energy comes from chemical reactions or light, and whether electrons come from the oxidation of organic or inorganic chemicals, nonfermentative energy conservation is always the result of electron transport reactions and the formation of a proton motive force (see Figure 3.22). The proton motive force is then used by ATPase to form ATP (Figure 3.20).

In earlier parts of this chapter we learned about the fundamental metabolic principles that govern aerobic and fermentative chemotrophs. Now we turn our attention to how these same fundamental principles apply to the vast diversity of metabolic types found in the microbial world. We return to this theme of catabolic diversity and explore its many facets in Chapter 14.

3.10 Anaerobic Respiration and Metabolic Modularity

Respiration can occur under both oxic (O_2 is present) and anoxic (O_2 is absent) conditions. The distinguishing feature between aerobic and anaerobic respiration is that aerobic respiration requires O_2 as the terminal electron acceptor, whereas **anaerobic respiration uses electron acceptors other than O_2** (Figure 3.22). Recall that when life began there was no O_2 in the atmosphere, and O_2 did not reach current levels until about 600 million years ago (Section 1.5). This means that anaerobic microbes dominated much of the history of life, and these organisms still occur widely today in any environment that lacks O_2 , such as wetlands, sediments, and in the guts of animals.

Figure 3.22 Metabolic diversity and its relationship to oxygen. (a) Chemoorganotrophs can be fermentative or engage in aerobic or anaerobic respiration, whereas (b) chemolithotrophs are typically respiratory. (c) Phototrophs are oxygenic if they generate O_2 by oxidizing H_2O and anoxygenic if they do not. Pmf, proton motive force.

Fermentative organisms and microbes that perform anaerobic respiration can both grow under anoxic conditions, and in this sense they are both anaerobes. However, these two forms of metabolism are distinct because all types of *respiration require an external electron acceptor and generate ATP primarily by oxidative phosphorylation*, whereas all types of *fermentation do not require an external electron acceptor and generate ATP by substrate-level phosphorylation*. We examine respiratory options in *Escherichia coli* now.

Respiration in *Escherichia coli*

E. coli is a metabolically versatile chemoorganotroph whose electron transport chain is similar to but not identical with that of *Paracoccus denitrificans* (Figure 3.19). *E. coli* can grow by aerobic respiration in the presence of O_2 , it can carry out fermentation in the absence of external electron acceptors, and it can grow by anaerobic respiration when nitrate is present in the absence of O_2 . As a result, *E. coli* can optimize its metabolism to grow under a range of conditions. When using an organic carbon source, *E. coli* will grow most rapidly by aerobic respiration, but under anaerobic conditions, as in an animal gut or in sediments, it can grow more rapidly by nitrate respiration than by fermentation, provided that nitrate is available. The energy *E. coli* can conserve during respiration is a function of the organization of its electron transport chain. *E. coli* can insert many different proteins in its electron transport chain, and this versatility allows it to conserve energy through respiration with a range of different electron donors and acceptors.

The basic organization of the *E. coli* respiratory chain (Figure 3.23) is Complex I followed by Complex II followed by *quinones* (for example, ubiquinone) and a *terminal reductase* that contains *b*-type and *o*-type cytochromes (in contrast to the *a*-type cytochromes of Complex IV). Depending on environmental conditions *E. coli* can swap out these components, employing alternative quinones (for example, ubiquinone or menaquinone), or employing alternative dehydrogenases or terminal reductases (*E. coli* has at least five sets of each). Note, however, that Complex III is missing from *E. coli* (Figure 3.23); this has energetic consequences.

The lack of Complex III means that during aerobic respiration, *E. coli* conserves less energy than *P. denitrificans*. For every 2 electrons that pass through its electron transport chain to O_2 , *E. coli* exchanges only 8 H^+ across the membrane while *P. denitrificans* exchanges 10 H^+ (compare Figures 3.19 and 3.23a). The free energy available to *P. denitrificans* and *E. coli* during the aerobic respiration of glucose is identical, but the organization of the electron transport chain in *P. denitrificans* allows it to conserve more energy than *E. coli*. This means that *P. denitrificans* will typically be able to outcompete *E. coli* for glucose if they are both growing aerobically. Hence, we can see that the amount of energy conserved by a respiratory organism is influenced by both bioenergetics and by the organization of its electron transport chain.

If nitrate is present in the absence of O_2 , *E. coli* will use *nitrate reductase* as its terminal reductase (Figure 3.23b). Nitrate reductase allows *E. coli* to perform anaerobic respiration with nitrate. However, the NO_3^-/NO_2^- couple is less electropositive than is the O_2/H_2O couple (Figure 3.4), and this is why anaerobic respiration provides less energy than aerobic respiration. This bioenergetic difference is reflected in the energy that can be conserved in electron transport, because only 6 H^+ are exchanged across the membrane for every 2 electrons passing to nitrate (rather than the 8 H^+ extruded aerobically, Figure 3.23). Likewise, for any given electron donor, aerobic organisms will always be able to conserve more energy—and will therefore outcompete—anaerobic organisms. However, oxygen is consumed very rapidly in poorly mixed aqueous environments because it is such a good electron acceptor and because it is poorly soluble in water. Hence, anoxic habitats and anaerobic microbes are widespread in nature and crucial to global biogeochemical cycles (Chapter 21).

Check Your Understanding

- If three bacteria were competing for glucose and one was capable only of aerobic respiration, one anaerobic respiration with nitrate (NO_3^-) as electron acceptor, and one anaerobic respiration with sulfate (SO_4^{2-}) as electron acceptor, which do

Figure 3.23 Respiration and nitrate-based anaerobic respiration in *Escherichia coli*. Electron transport processes in the membrane of *E. coli* when (a) O_2 or (b) NO_3^- is used as terminal electron acceptor. Note the difference in the number of protons translocated with the different terminal electron acceptors and compare these to the difference in the energetics of these reactions when glucose is the electron donor (see Figure 3.4). you think would be most competitive in an oxic environment?
In an anoxic environment? (Hint: Review Figure 3.4 and Table 3.1.)

- Explain why *Paracoccus denitrificans* would outcompete *Escherichia coli* if both organisms were competing for glucose in the presence of O_2 .
- If respiratory metabolism always conserves more energy than fermentative metabolism, then why are fermentative organisms so common?

3.11 Chemolithotrophy and Phototrophy

Thus far in this chapter we have focused on chemoorganotrophs, chemotrophic organisms that rely on organic electron donors. Now we will focus on *chemolithotrophs*, which use inorganic electron donors, and on *phototrophs*, which get their energy from light (Figure 3.3). Chemolithotrophs can be aerobes or anaerobes and they are found in a wide range of environments, most anywhere that reduced inorganic compounds are present.

Chemolithotrophy

Examples of common inorganic electron donors that fuel chemolithotrophic metabolisms include H_2S , H_2 , Fe^{2+} , and NH_4^+ (Figure 3.22). Chemolithotrophic metabolisms begin with the oxidation of an inorganic electron donor and with the electrons entering an electron transport chain. For example, the hydrogen bacterium *Ralstonia eutropha* grows as an aerobic chemolithotroph with H_2 as its electron donor ($2 H^+/H_2$, $-0.42 V$). *R. eutropha* has a membrane-bound hydrogenase that splits H_2 in the periplasm and reduces quinones in the electron transport chain (Figure 3.24). Electron transport then generates a proton motive force, as we have already seen for the oxidation of organic electron donors by chemoorganotrophs (Figures 3.19 and 3.23). Cells of *R. eutropha* actually have two hydrogenases (Figure 3.24). The membrane-bound hydrogenase contributes to energy conservation, as we have described, whereas the soluble hydrogenase, which is present in the cytoplasm, is used to reduce NAD^+ to NADH needed for autotrophic growth

(Figure 3.24). This reduction is possible because the E_0' of the $2 H^+/H_2$ couple is more electronegative than the E_0' of the $NAD^+/NADH$ couple (Figure 3.4).

Respiration by chemoorganotrophs and chemolithotrophs are united by their dependence on oxidative phosphorylation for energy conservation. Just as we saw for anaerobic respiration, the energy available to chemolithotrophs depends on the $\Delta E_0'$ between the electron-donating and electron-accepting reactions (Figure 3.4). Like many chemoorganotrophs, many chemolithotrophs can have either aerobic or anaerobic metabolisms (Figure 3.22). Indeed, almost any combination of electron donor and electron acceptor can sustain life if these reactions are coupled to an electron transport chain used in oxidative phosphorylation and if the $\Delta E_0'$ of the redox reaction releases sufficient free energy to form ATP.

One major difference between chemoorganotrophs and chemolithotrophs is in their source of cellular carbon. Chemoorganotrophs are heterotrophs and therefore use organic compounds (glucose, acetate, etc.) as carbon sources. These organic compounds are readily converted into cellular materials during biosynthetic reactions. By contrast, chemolithotrophs typically use carbon dioxide (CO_2) as a carbon source and are therefore autotrophs (we describe a major autotrophic pathway—the Calvin cycle—in Section 3.12). Autotrophy requires a significant amount of reducing power (Figure 3.1) such as NADH, but the electron donors used by chemolithotrophs often have a more electropositive E_0' than does $NADH/NAD^+$ (Figure 3.4). How do such chemolithotrophs form NADH? In the case of *R. eutropha*, we saw that a cytoplasmic hydrogenase is used to form NADH directly from NAD^+ and H_2 (Figure 3.24). However, most chemolithotrophs lack hydrogenases and solve this problem by employing *reverse electron transport*, an energy-consuming process that we will learn about in the context of phototrophy.

Phototrophy

In the process of photosynthesis, carried out by *phototrophs*, light energy is used instead of chemical reactions to drive electron flow and generate a proton motive force. During these events, ATP

Figure 3.24 Energy conservation in *Ralstonia eutropha*, an autotrophic chemolithotroph that oxidizes H_2 . (a) In *R. eutropha*, two hydrogenases are present; the membrane-bound hydrogenase participates in electron transport, whereas the soluble hydrogenase makes NADH for the Calvin cycle (see Section 3.12). Cyt, cytochrome; Q, quinone. For details of the Q-cycle, see Figure 3.19. (b) Transmission electron micrograph of negatively stained cells of *R. eutropha*. A cell is about $0.6\ \mu\text{m}$ in diameter and contains several flagella.

synthase generates ATP by *photophosphorylation* (Figure 3.25a), the light-driven analog of oxidative phosphorylation. Phototrophs can be either *oxygenic* (for example cyanobacteria, algae, and plants) or *anoxygenic* (diverse types of *Bacteria*), depending on whether or not the process generates O_2 as a waste product from the oxidation of H_2O (Figure 3.22). Anoxygenic phototrophs evolved long before oxygenic phototrophs (◀ Section 1.5), and there is far more metabolic diversity among the anoxygenic phototrophs than among oxygenic phototrophs. However, light-driven photoreactions in both oxygenic and anoxygenic phototrophs operate on many of the same principles.

Purple bacteria are one type of anoxygenic phototrophs, which are common in anoxic aquatic environments (Figure 3.25b). Like all phototrophic organisms, purple bacteria produce a **photosynthetic reaction center** that converts light energy into chemical energy (ATP, Figure 3.25a). While we focus here primarily on energy conservation during photophosphorylation, we will learn more about the operation of photosynthetic reaction centers in Chapter 14. All reaction centers contain photopigments such as chlorophylls or bacteriochlorophylls, which are structurally similar to heme molecules (▶ Section 14.3).

Phototrophs use photopigments to absorb light energy and transfer this energy to the photosynthetic reaction center (Figure 3.25a). The reaction center in purple bacteria uses the energy from light to convert a form of bacteriochlorophyll *a* called *P870*, which is a relatively weak electron donor, into a very strong electron donor (E_0' near -1.0 V) called *P870**. The excited *P870** then donates two electrons to a quinone within the cytoplasmic membrane. The reduced quinone in turn donates its electrons to the *cytochrome bc₁* complex, which is similar in structure and function to the Complex III we saw in oxidative phosphorylation (Figure 3.19). The net result is photophosphorylation, which results when light energy is used to

generate a proton motive force that is harnessed by ATP synthase to make ATP (Figure 3.25a).

A major difference between respiratory electron transport and photosynthetic electron transport in purple bacteria is that in purple bacteria electrons from cytochrome *bc₁* are not transferred to an external electron acceptor (such as O_2). Instead the electrons are passed to cytochrome *c* and then back to *P870*, returning it to its original E_0' . Hence, purple bacteria reuse the same electrons over and over again to make ATP as long as light is present to fuel the initial $P870 \rightarrow P870^*$ transition. This process is called *cyclic photophosphorylation* because electrons move within a closed loop. We consider other aspects of photosynthesis, including the differences between anoxygenic photosynthesis and oxygenic photosynthesis, in Chapter 14.

Generation of Reducing Power

For purple bacteria and chemolithotrophs to grow autotrophically, the formation of ATP is not enough. Reducing power (NADH) is also necessary to produce cellular material. Reducing power can come from many different electron donors. Many purple bacteria and chemolithotrophs use reduced sulfur compounds such as H_2S as their electron donors. However, the E_0' of S^0/H_2S (-0.28 V) is insufficiently electronegative to reduce NAD^+ (-0.32 V); hence, these bacteria cannot make NADH directly from H_2S . These organisms solve this problem by pushing electrons from the quinone pool backwards (against the electrochemical gradient) towards a dehydrogenase-like protein (similar to Complex I) so that they reduce NAD^+ to NADH. This process, called *reverse electron transport*, requires energy and is driven by dissipation of the proton motive force. We will see this pattern once more when we discuss biosynthetic reactions, in which the reversibility of reactions and pathways is often used to synthesize a great diversity of biomolecules.

(a) Electron transport in purple bacteria

Figure 3.25 Electron flow in anoxygenic photosynthesis in a purple bacterium. (a) Energy conservation in purple bacteria results from cyclic photophosphorylation. The photosynthetic reaction center uses light energy to energize electrons for use in electron transport and the generation of proton motive force. Four protons are translocated for every two electrons that

pass from the reaction center to cytochrome bc_1 . P870 is a form of bacteriochlorophyll a in the ground state and is a fairly electropositive electron donor. P870* is formed after light excitation of P870 and is a strongly electronegative electron donor. - What is reverse electron transport, and why is it unnecessary for chemoorganotrophs?

IV • Biosynthesis

Biosynthesis encompasses the anabolic reactions that produce cellular materials and requires ATP and building blocks composed of C, N, and other elements obtained from organic or inorganic sources.

We conclude this chapter with an overview of how the monomers that make up the four classes of cellular macromolecules are biosynthesized and also look at how polysaccharides and lipids are biosynthesized in a general way. The biosynthesis of *informational* macromolecules—proteins and nucleic acids—is the theme of Chapter 6. Collectively, these biosynthetic reactions are that aspect of metabolism we call *anabolism*.

All cells require a source of carbon and nitrogen to perform biosynthetic reactions. The atmosphere contains a large reservoir of inorganic carbon as CO_2 , and nitrogen as N_2 . However, these gases must be chemically reduced before they can be assimilated into cell

material. The reductive processes associated with the assimilation of CO_2 and N_2 are called CO_2 fixation and N_2 fixation, respectively. Both of these pathways require substantial amounts of energy from the cell in the form of ATP and reducing power. These processes evolved very early in the history of life and they are widely distributed among species of *Bacteria* and *Archaea*.

3.12 Autotrophy and Nitrogen Fixation

Many phototrophic and chemolithotrophic microbes get the carbon they need, and in some cases the nitrogen they need, by reducing CO_2 and N_2 , respectively, from air. Because CO_2 and N_2 are such highly oxidized molecules, their assimilation into cell material requires large amounts of ATP and reducing power (Figure 3.1). Here we consider the assimilation of CO_2 —autotrophy—only in the context of the Calvin cycle. In Chapter 14 we will see that autotrophy shows considerable metabolic diversity beyond the Calvin cycle.

The Calvin Cycle

In many autotrophic organisms, including all oxygenic phototrophs, the carbon needed for biosynthesis is derived from the reduction of CO_2 by the **Calvin cycle** (Figure 3.26). The Calvin cycle is present in phototrophic purple bacteria (Figure 3.25b), cyanobacteria, algae, green plants, most chemolithotrophic *Bacteria*, and a few *Archaea*. The cycle requires CO_2 , a CO_2 -acceptor molecule, NADPH, ATP, and two key enzymes, *ribulose biphosphate carboxylase* and *phosphoribulokinase*.

The first step in the Calvin cycle is catalyzed by the enzyme *ribulose biphosphate carboxylase*, **RuBisCO** for short. RuBisCO catalyzes the

Figure 3.26 Key reactions of the Calvin cycle. (a) Reaction of the enzyme ribulose biphosphate carboxylase. (b) Steps in the conversion of 3-phosphoglycerate (PGA) to glyceraldehyde 3-phosphate. Note that both ATP and NADPH are required. (c) Conversion of ribulose 5-phosphate to the CO_2 acceptor molecule ribulose 1,5-bisphosphate by the enzyme phosphoribulokinase.

formation of two molecules of 3-phosphoglycerate (PGA, a C_3 compound) from ribulose biphosphate (a C_5 compound) and CO_2 as shown in Figure 3.26a. The PGA is then phosphorylated and reduced to a key intermediate of glycolysis, glyceraldehyde 3-phosphate. From this, glucose can be formed by reversal of the early steps in glycolysis (Figure 3.11).

Instead of focusing on the incorporation of a single molecule of CO_2 , it is easiest to consider Calvin cycle reactions based on the incorporation of 6 molecules of CO_2 , as this is what is required to make one hexose ($C_6H_{12}O_6$). For RuBisCO to incorporate 6 molecules of CO_2 , 6 molecules of ribulose biphosphate (total, 30 carbons) are required; carboxylation of these yields 12 molecules of PGA (total, 36 carbons) (Figure 3.27). A series of biochemical rearrangements between various sugars follows, resulting in 6 molecules of ribulose 5-phosphate (30 carbons) plus one hexose (6 carbons) for cell biosynthesis. The final step in the Calvin cycle is the phosphorylation of each ribulose 5-phosphate by the enzyme *phosphoribulokinase* (Figures 3.26c and 3.27) to regenerate 6 molecules of the acceptor molecule, ribulose biphosphate. All totaled, 12 NADPH and 18 ATP are required to synthesize one glucose from 6 CO_2 by the Calvin cycle.

Although the Calvin cycle is the most widespread and important pathway of CO_2 fixation in the biosphere, many autotrophic *Bac-*

teria and *Archaea* have evolved alternative pathways for fixing CO_2 . These alternative autotrophic pathways typically reduce CO_2 to the level of acetyl-coenzyme A (acetyl-CoA), a central metabolite that feeds into all major biosynthetic pathways (Section 3.6). We will learn about these alternative pathways for CO_2 fixation in Chapter 14 when we once again consider metabolic diversity.

Nitrogen Fixation

In addition to carbon, cells need a significant amount of nitrogen to synthesize proteins, nucleic acids, and many other organic molecules. Most microbes obtain this nitrogen from “fixed” forms of nitrogen in their environment, such as ammonia (NH_3) or nitrate (NO_3^-). However, many *Bacteria* and *Archaea* can form ammonia from gaseous dinitrogen (N_2), a process called **nitrogen fixation** (Figure 3.28). The process of nitrogen fixation is of enormous ecological and agricultural importance (Section 1.6) as it provides much of the fixed nitrogen that supports global ecosystems and is important to leguminous crops, such as soybeans, lentils, and alfalfa, which form symbiotic associations with nitrogen-fixing bacteria (Section 23.4).

Nitrogen fixation is catalyzed by the enzyme complex **nitrogenase**. Nitrogenase consists of two proteins, *dinitrogenase* and *dinitrogenase reductase* (Figure 3.28). Both proteins contain iron, and

Figure 3.27 The Calvin cycle. Shown is the production of one hexose molecule from six CO_2 . For each six molecules of CO_2 incorporated, one fructose 6-phosphate is produced that can be drawn off for biosynthesis. In phototrophs, the energy to produce ATP comes from light; in chemolithotrophs, the energy to produce ATP comes from the oxidation of inorganic electron donors. In oxygenic phototrophs, electrons for NAD(P)H come from water; in anoxygenic phototrophs, the electrons come from reduced substances such as H_2S . In chemolithotrophs, NAD(P)H is formed from inorganic electron donors.

dinitrogenase contains molybdenum as well. The iron and molybdenum in dinitrogenase are part of the enzyme cofactor called the *iron-molybdenum cofactor* (*FeMo-co*), and reduction of N_2 occurs at this site. Owing to the stability of the triple bond in N_2 , its activation and reduction is very energy demanding. Six electrons are needed to reduce N_2 to NH_3 , and the successive reduction steps occur directly on nitrogenase with no free intermediates accumulating. The electrons for N_2 reduction are transferred to dinitrogenase reductase from low-potential iron-sulfur proteins such as flavodoxin (or ferredoxin) (Table 3.1). The sequence of electron transfer in nitrogenase is: electron donor $\rightarrow$ dinitrogenase reductase $\rightarrow$ dinitrogenase $\rightarrow \text{N}_2$ (Figure 3.28). Although only six electrons are necessary to reduce N_2 to two NH_3 , eight electrons are actually consumed in the process, two electrons being lost as H_2 for each molecule of N_2 reduced. For unknown reasons, H_2 evolution is an obligatory step in nitrogen fixation and occurs in the first step of the nitrogenase reduction cycle.

In addition to electrons, ATP is required for nitrogen fixation. ATP binds to dinitrogenase reductase, and, following its hydrolysis to ADP, lowers the reduction potential of the protein. This allows dinitrogenase reductase to interact with and reduce dinitrogenase. Electrons are transferred from dinitrogenase reductase to dinitrogenase one at a time, and each cycle of reduction requires two ATP. Thus, a total of 16 ATP are required for the reduction of N_2 to 2 NH_3 (Figure 3.28).

Figure 3.28 Biological nitrogen fixation by nitrogenase. The nitrogenase complex is composed of dinitrogenase and dinitrogenase reductase. Electrons from reduced flavodoxin (or ferredoxin) are used to reduce dinitrogenase reductase, and this enzyme in turn reduces dinitrogenase at the expense of ATP. Dinitrogenase ultimately donates electrons to N_2 at the active site of the enzyme, resulting in the formation of 2 NH_3 . H is hydrogen (which consists of $\text{H}^+ + \text{e}^-$).

Nitrogenase is inhibited by oxygen (O_2), but many nitrogen-fixing bacteria are obligate aerobes. In these organisms, nitrogenase is protected from oxygen inactivation by a combination of the rapid removal of O_2 by respiration and the production of O_2 -retarding slime layers on the outer cell surface (Figure 3.29). In certain cyanobacteria, the nitrogenase enzyme is protected from O_2 by its localization in a differentiated cell called a *heterocyst* (Figure 3.29c; ► Section 15.3). Inside the heterocyst, conditions are anoxic despite the fact that photosynthesis and O_2 production occur in neighboring vegetative cells. Oxygen is not produced in the heterocyst, and this protects nitrogenase so that it can fix N_2 into organic nitrogen compounds, which are then shared with adjacent photosynthetic cells (► Section 8.9).

Check Your Understanding

- How many electrons and how much ATP are required to make one hexose molecule by the Calvin cycle?
- How many electrons and how much ATP are required to fix one molecule of N_2 into two of NH_3 ?
- Describe two ways in which N_2 -fixing organisms can protect their nitrogenase from O_2 .

Figure 3.29 Two ways of protecting nitrogenase from O_2 . Induction of slime formation by O_2 is demonstrated by comparing transmission electron micrographs of (a) nitrogen-fixing *Azotobacter vinelandii* cells grown with 2.5% O_2 and showing very little slime with (b) nitrogen-fixing *A. vinelandii* cells grown in air (21% O_2) and showing an extensive, darkly staining slime layer (arrow). The slime retards diffusion of O_2 into the cell, thus preventing nitrogenase inactivation by O_2 . A single cell of *A. vinelandii* is about 2 μm in diameter. (c) Fluorescence photomicrograph of cells of the filamentous cyanobacterium *Anabaena* showing a single heterocyst (green). The heterocyst is a thick-walled differentiated cell that does not produce O_2 but instead specializes in nitrogen fixation and protects nitrogenase from O_2 inactivation.

Figure 3.30 Sugar metabolism. (a) Polysaccharides are synthesized from activated forms of hexoses such as UDPG. (b) Gluconeogenesis. When glucose is needed, it can be biosynthesized from other carbon compounds by reversing the steps in glycolysis. (c) Pentoses for nucleic acid synthesis are formed by decarboxylation of hexoses such as glucose 6-phosphate. Note how the precursors of DNA are produced from the precursors of RNA by the enzyme ribonucleotide reductase.

3.13 Sugars and Polysaccharides

Polysaccharides are key components of microbial cell walls, and cells often store carbon and energy reserves in the form of the polysaccharides glycogen or starch (Chapter 2). How are such large molecules made?

Polysaccharide Biosyntheses and Gluconeogenesis

Polysaccharides are synthesized from *activated* forms of glucose, either uridine diphosphoglucose (UDPG; **Figure 3.30a**) or adenosine diphosphoglucose (ADPG). UDPG is the precursor of several glucose derivatives used in the biosynthesis of important structural polysaccharides, such as *N*-acetylglucosamine and *N*-acetylmuramic acid in peptidoglycan or the lipopolysaccharide component of the gram-negative outer membrane (◀ Sections 2.3 and 2.4). Polysaccharides are biosynthesized by adding activated glucose to a preexisting polymer fragment. For example, glycogen is synthesized as $ADPG + \text{glycogen} \rightarrow ADP + \text{glycogen-glucose}$.

When a cell is growing on a hexose such as glucose, obtaining glucose for polysaccharide synthesis is obviously not a problem. But when the cell is growing on other carbon compounds, glucose must be biosynthesized. This process, called *gluconeogenesis*, uses phosphoenolpyruvate, one of the intermediates of glycolysis, as a starting material and travels backwards through the glycolytic pathway (**Figure 3.11**) to form glucose. Phosphoenolpyruvate can also be synthesized from oxaloacetate, a citric acid cycle intermediate (**Figure 3.12**). An overview of gluconeogenesis is shown in **Figure 3.30b**.

Pentose Metabolism and the Pentose Phosphate Pathway

Pentoses (C_5 sugars) are formed by the removal of one carbon atom from a hexose, typically as CO_2 . The pentoses needed for nucleic acid synthesis, ribose (in RNA) and deoxyribose (in DNA), are formed as shown in **Figure 3.30c**. The enzyme *ribonucleotide reductase*

Figure 3.31 Pentose phosphate pathway. This pathway generates pentoses from other sugars for biosynthesis and also functions to catabolize pentose sugars. (a) Production of the key intermediate, ribulose 5-phosphate. (b) Other reactions in the pentose phosphate pathway.

converts ribose into deoxyribose by reduction of the hydroxyl (–OH) group on the 2' carbon of the 5-carbon pentose ring (► Section 6.1 and Figure 6.1b). This reaction occurs after, not before, synthesis of nucleotides. Thus, *ribonucleotides* are biosynthesized, and some of them are later reduced to *deoxyribonucleotides* for use as precursors of DNA.

The major pathway for pentose production is the **pentose phosphate pathway** (Figure 3.31). In this pathway, glucose, a hexose, is oxidized to CO₂, NADPH, and the key intermediate, *ribulose 5-phosphate*; from the latter, several different pentose derivatives can be formed. When pentoses are used as electron donors for energy conservation, they feed directly into the pentose phosphate pathway, typically becoming phosphorylated to form ribose phosphate or a related compound before being further catabolized (Figure 3.31b).

Besides its importance in pentose metabolism, the pentose phosphate pathway is also responsible for producing many other important sugars in the cell, including those containing 4 to 7 carbons. These sugars can eventually be converted to hexoses for either catabolic or biosynthetic purposes (Figures 3.30 and 3.31). A final important role of the pentose phosphate pathway is that it generates NADPH, a coenzyme used in many biosyntheses and in particular as a reductant for the production of deoxyribonucleotides (Figure 3.30c) and in the biosynthesis of fatty acids (see Figure 3.35). Although most cells have an exchange mechanism for converting NADH into NADPH, the pentose phosphate pathway is the major means by which NADPH is synthesized directly.

Check Your Understanding

- What form of activated glucose is used in the biosynthesis of glycogen by bacteria?
- What is gluconeogenesis?
- What functions does the pentose phosphate pathway play in the cell?

3.14 Amino Acids and Nucleotides

The monomers in proteins and nucleic acids are the amino acids and nucleotides, respectively. Their biosyntheses are typically multistep biochemical pathways that we need not consider in detail here. Instead, we identify the carbon skeletons needed for the biosynthesis of amino acids and nucleotides, look at their origins in pathways we have already considered, and summarize the mechanisms by which they are made.

Monomers of Proteins: Amino Acids

Organisms that cannot obtain some or all of their amino acids preformed from the environment must synthesize them from glucose or other carbon sources. Amino acids are grouped into structurally related *families* that share several biosynthetic steps. The carbon skeletons for amino acids come almost exclusively from intermediates of glycolysis (Figure 3.11) or the citric acid cycle (Figure 3.12) (Figure 3.32).

The amino group (–NH₂) of amino acids is typically derived from an inorganic nitrogen source, such as ammonia (NH₃). Ammonia is

Figure 3.32 Amino acid families. Glycolysis (a) and the citric acid cycle (b) provide the carbon skeletons for most amino acids. Synthesis of the various amino acids in a family may require many steps starting with the parent amino acid (shown in bold as the name of the family).

most often incorporated during biosynthesis of the amino acids glutamate or glutamine by the enzymes *glutamate dehydrogenase* and *glutamine synthetase*, respectively (Figure 3.33). When NH_3 is present at high levels, glutamate dehydrogenase or other amino acid dehydrogenases are used. However, when NH_3 is present at low levels, glutamine synthetase, with its energy-consuming reaction mechanism (Figure 3.33b) and correspondingly high affinity for its substrates, is employed. The enzymes glutamate dehydrogenase and glutamine synthetase are present in most *Bacteria* and *Archaea*.

Once ammonia is incorporated into glutamate or glutamine, the amino group of these amino acids can be transferred to other carbon skeletons to form other nitrogenous compounds. For example, glutamate can donate its amino group to oxaloacetate in a transaminase reaction, producing α -ketoglutarate and aspartate (Figure 3.33c). Alternatively, glutamine can react with α -ketoglutarate to form two molecules of glutamate in an aminotransferase reaction (Figure 3.33d). The end result of these types of reactions is the shuttling of ammonia into various carbon skeletons from which further biosynthetic reactions occur to form all of the amino acids needed to make proteins and other nitrogen-containing biomolecules.

Monomers of Nucleic Acids: Nucleotides

The biochemistry behind purine and pyrimidine biosynthesis is quite complex and so only an outline of their biosyntheses is necessary here. Purines are constructed literally atom by atom from several carbon and nitrogen sources, including even CO_2 (Figure 3.34). The purine nucleotide skeleton, inosinic acid (Figure 3.34b), is the precursor of the purine nucleotides *adenine* and *guanine*. Once these are synthesized (in their triphosphate forms) and attached to ribose, they are ready to be incorporated into DNA (following ribonucleotide reductase activity, Figure 3.30c) or RNA.

Like the purine ring, the pyrimidine ring is also constructed from several sources (Figure 3.34c). From the pyrimidine nucleotide skeleton uridylate (Figure 3.34d), all of the pyrimidines—*thymine*, *cytosine*, and *uracil*—are derived. Structures of all the purines and pyrimidines are shown in Chapter 6 (► Figure 6.1c).

Figure 3.33 Ammonia incorporation in bacteria. Ammonia (NH_3) and the amino groups of all amino acids are shown in green. Two major pathways for NH_3 assimilation in bacteria are those catalyzed by the enzymes (a) glutamate dehydrogenase and (b) glutamine synthetase. (c) Transaminase reactions transfer an amino group from an amino acid to an organic acid. (d) The enzyme glutamate synthase forms two glutamates from one glutamine and one α -ketoglutarate.

Figure 3.34 Biosynthesis of purines and pyrimidines. (a) Components of the purine skeleton, labeled with their sources. (b) Inosinic acid, the precursor of all purine nucleotides. (c) Components of the pyrimidine skeleton, orotic acid, labeled with their sources. (d) Uridylate, the precursor of all pyrimidine nucleotides. Uridylate is formed from orotate following a decarboxylation and the addition of ribose 5-phosphate.

Check Your Understanding

- What is an amino acid family?
- List the steps required for the cell to incorporate NH_3 into amino acids.
- Which nitrogen bases are purines and which are pyrimidines?

3.15 Fatty Acids and Lipids

Lipids are major components of the cytoplasmic membrane and of the outer membrane of gram-negative bacteria; lipids can also be carbon and energy reserves. Fatty acids are the backbone of microbial lipids. However, recall that fatty acids, per se, are found only in *Bacteria* and *Eukarya*. *Archaea* do not contain fatty acids in their lipids but instead have hydrophobic isoprenoid side chains that play a similar structural role (Chapter 2). Our focus here is on the biosynthesis of fatty acids in *Bacteria*.

Fatty Acid Biosynthesis

Fatty acids are biosynthesized two carbon atoms at a time by the activity of a protein called *acyl carrier protein* (ACP). ACP holds the growing fatty acid as it is being constructed and releases it once it has reached its final length (Figure 3.35). Although fatty acids are constructed *two* carbons at a time, each C_2 (acetyl) unit originates

Figure 3.35 The biosynthesis of the C₁₆ fatty acid palmitate. The condensation of acetyl-ACP (which is formed from acetyl-CoA) and malonyl-ACP forms acetoacetyl-ACP. ACP (acyl carrier protein) is a small protein used to add carbon subunits to a growing fatty acid chain. Each successive addition of an acetyl unit comes from malonyl-ACP.

from the *three*-carbon compound *malonate*, which is attached to the ACP to form malonyl-ACP. As each malonyl residue is donated, one molecule of CO₂ is released (Figure 3.35).

In addition to saturated, even-carbon-number fatty acids, fatty acids can also be unsaturated, branched, or have an odd number of carbon atoms. Unsaturated fatty acids contain one or more double bonds in the long hydrophobic portion of the molecule. The number and position of these double bonds is often species-specific or

group-specific, and the double bonds are formed by desaturation of a saturated fatty acid. Branched-chain fatty acids are biosynthesized using a branched-chain initiating molecule, and odd-carbon-number fatty acids (for example, C₁₃, C₁₅, C₁₇) are biosynthesized using an initiating molecule that contains a propionyl (C₃) group instead of acetyl.

The fatty acid composition of cellular lipids varies from species to species and can also vary in a given organism with differences in growth temperature. Cells adjust their fatty acid composition primarily to keep the cytoplasmic membrane from getting either too stiff in the cold or too fluid as temperatures rise. Growth at low temperatures promotes the biosynthesis of shorter-chain and unsaturated fatty acids, whereas growth at higher temperatures promotes the biosynthesis of longer-chain and more saturated fatty acids. The most common fatty acids in lipids of *Bacteria* are those with chain lengths of C₁₂–C₂₀.

Lipid Biosynthesis

In the assembly of lipids in cells of *Bacteria* and *Eukarya*, fatty acids are first added to a molecule of glycerol. For simple triglycerides (fats), all three glycerol carbons are esterified with fatty acids. To form complex lipids, one of the carbon atoms in glycerol is embellished with a molecule of phosphate, ethanolamine, carbohydrate, or some other polar substance (◀ Figure 2.1c). In *Archaea*, although membrane lipids are constructed from isoprene to form the phytanyl (C₁₅) or biphytanyl (C₃₀) side chains, the glycerol backbone of archaeal membrane lipids contains a polar group (sugar, phosphate, sulfate, or polar organic compound) as for the lipids of *Bacteria* and *Eukarya*. Polar groups are important in lipids for forming the canonical membrane architecture: a hydrophobic interior with hydrophilic inner and outer surfaces (◀ Section 2.1 and Figures 2.1 and 2.2).

Check Your Understanding

- Explain how fatty acids are constructed two carbon atoms at a time while the immediate donor of these carbons is a three-carbon compound.
- What differences exist in lipids from the three domains of life?
- What is the result of adding a polar head group to lipids?

Go to **Mastering Microbiology** for videos, animations, practice tests, and more.

CHAPTER REVIEW

I • Fundamentals of Metabolism

- 3.1** All cells require water, carbon and other nutrients, free energy, and reducing power. Microorganisms conserve energy either from the oxidation of chemicals or from light. Chemoorganotrophs use organic chemicals as their electron donors, while chemolithotrophs use inorganic chemicals. Phototrophic organisms convert light energy into chemical

energy (ATP) and include both oxygenic and anoxygenic species.

Q When a microorganism is growing on glucose as both an energy and a carbon source, to which energy and carbon utilization classes does it belong? When a microorganism can synthesize its own organic compounds from carbon dioxide when growing on H₂, to which energy and carbon utilization classes does it belong?

- 3.2** Oxidation–reduction reactions require electron donors and electron acceptors. The tendency of a compound to accept or release electrons is expressed by its reduction potential (E_0'). Redox reactions in a cell often employ redox coenzymes such as NAD^+/NADH as electron shuttles.

Q The following is a series of coupled electron donors and electron acceptors (written as donor:acceptor). Using the data in Table 3.1 and Figure 3.4, order this series from most energy yielding to least energy yielding: $\text{H}_2:\text{Fe}^{3+}$, $\text{NO}:\text{Mn}^{4+}$, $\text{H}_2\text{S}:\text{O}_2$, methanol: NO_3^- (producing NO_2^-), $\text{H}_2:\text{O}_2$, $\text{Fe}^{2+}:\text{O}_2$, $\text{NO}_2^-:\text{Fe}^{3+}$ (producing NO_3^-), and $\text{H}_2\text{S}:\text{NO}_3^-$.

- 3.3** Chemical reactions in the cell are accompanied by changes in energy, expressed in kilojoules per mole. Reactions either release or consume free energy. $\Delta G^{0'}$ is a measure of the energy released (if $\Delta G^{0'}$ is negative in arithmetic sign) or consumed (if $\Delta G^{0'}$ is positive in arithmetic sign) in a reaction under standard conditions and reveals which reactions can be used by an organism to conserve energy.

Q Calculate $\Delta G^{0'}$ for the following reaction: glucose + $6\text{O}_2 \rightarrow 6\text{CO}_2 + 6\text{H}_2\text{O}$. Is this reaction exergonic or endergonic? Distinguish between $G^{0'}$, G , and $G_f^{0'}$.

- 3.4** Energy is conserved in compounds that contain energy-rich phosphate or sulfur bonds. The most common of these compounds is ATP, the prime energy carrier in the cell. ATP can be formed by substrate-level phosphorylation, oxidative phosphorylation, or photophosphorylation.

Q Why is acetyl phosphate considered an energy-rich compound while glucose 6-phosphate is not? What are the primary mechanisms of ATP formation in fermentative metabolism and respiratory metabolism, respectively?

- 3.5** Enzymes are protein catalysts that increase the rate of biochemical reactions by activating the substrates that bind to their active site. Enzymes are highly specific in the reactions they catalyze, and this specificity resides in the three-dimensional structures of the polypeptide(s) that make up the protein(s).

Q What makes enzymes highly specific?

II • Catabolism: Chemoorganotrophs

- 3.6** The glycolytic pathway is used to break down glucose to pyruvate. The citric acid cycle oxidizes pyruvate to CO_2 and releases electrons for the electron transport chain and is also a source of biosynthetic intermediates. The glyoxylate cycle is necessary for the catabolism of two-carbon electron donors, such as acetate.

Q Why are glycolysis and the citric acid cycle, on their own, insufficient to sustain life? What else is needed?

- 3.7** In the absence of external electron acceptors, organic compounds can be catabolized anaerobically only by fermentation. Fermentations require that an energy-rich organic compound be formed that can yield ATP by substrate-level phosphorylation. Redox balance is achieved by the production of fermentation products.

Q Define the term substrate-level phosphorylation. How does it differ from oxidative phosphorylation? What compound(s) do fermentative bacteria need to synthesize in order to make ATP by substrate-level phosphorylation?

- 3.8** Electron transport chains are composed of membrane-associated redox proteins that are arranged in order of their increasing E_0' values. The electron transport chain functions in a concerted fashion to carry electrons from the primary electron donor to the terminal electron acceptor, which is O_2 in aerobic respiration.

Q What is the value to the electron transport chain of alternating between electron carriers that carry only electrons and those that carry electrons and protons?

- 3.9** During electron transport, protons are extruded to the outside of the membrane to form the proton motive force. Key electron carriers include flavins, quinones, the cytochrome bc_1 complex, and other cytochromes. The cell uses the proton motive force to make ATP through the activity of ATPase.

Q How is the proton motive force generated during electron transport? How do cells generate ATP from a proton motive force?

III • Catabolism: Electron Transport and Metabolic Diversity

- 3.10** When conditions are anoxic, several electron acceptors can substitute for O_2 in anaerobic respiration. During respiration, energy is conserved by the transport of electrons through the electron transport chain that generates a proton motive force; ATP is synthesized by ATP synthase by dissipating the proton motive force.

Q *E. coli* can oxidize glucose to 6CO_2 and $6\text{H}_2\text{O}$ by aerobic respiration or by anaerobic respiration with nitrate. How much ATP would it form per glucose oxidized in each circumstance?

- 3.11** Chemolithotrophs use inorganic compounds as electron donors to drive electron transport reactions and thereby generate a proton motive force. Phototrophs use light energy to drive electron transport reactions and thereby generate a proton motive force. The proton motive force underlies energy conservation in all forms of respiration and photosynthesis.

Q What is the role of electron transport in cyclic photophosphorylation? If a purple bacterium is performing cyclic photophosphorylation and growing autotrophically, why would it need an electron donor?

IV • Biosynthesis

- 3.12** Autotrophy is supported in most phototrophic and chemolithotrophic bacteria by the Calvin cycle, in which the enzyme RuBisCO plays a key role. The reduction of N_2 to NH_3 is called nitrogen fixation and is catalyzed by the enzyme nitrogenase.

Q How might the ability to fix CO_2 and N_2 help a bacterium be more competitive in its environment?

- 3.13** Polysaccharides are important structural components of cells and are biosynthesized from activated forms of their monomers. Gluconeogenesis is the production of glucose from nonsugar precursors.

Q What is the importance of the enzyme ribonucleotide reductase in the metabolism of sugars? What is the difference between “free” and “activated” glucose?

- 3.14** Amino acids are formed from carbon skeletons to which ammonia is added from glutamate, glutamine, or a few other amino acids. Nucleotides are biosynthesized using carbon skeletons from several different sources.

Q Name two common enzymes that function to incorporate NH_3 into the cell. How do their reaction mechanisms differ?

- 3.15** Fatty acids are synthesized from the three-carbon precursor malonyl-ACP, and fully formed fatty acids are attached to glycerol to form lipids. Only the lipids of *Bacteria* and *Eukarya* contain fatty acids.

Q Describe the process by which a fatty acid such as palmitate (a C_{16} straight-chain saturated fatty acid) is synthesized in a cell.

APPLICATION QUESTIONS

1. For the following reactions identify the electron donor and the electron acceptor, define the type of metabolism and whether the reaction is aerobic or anaerobic, and calculate the free-energy change under standard conditions (see Sections 3.2 and 3.3):

2. Using the data in Figure 3.4, predict the sequence of electron carriers in the electron transport chain of an organism growing aerobically that has the following electron carriers: ubiquinone, cytochrome *a*, cytochrome *b*, NADH, cytochrome *c*, FAD.

3. Explain the following observation in light of the redox tower: Cells of *Escherichia coli* fermenting glucose grow faster when NO_3^- is supplied to the culture (NO_2^- is produced), and then grow even faster (and stop producing NO_2^-) when the culture is highly aerated. Calculate the standard free-energy change of the relevant metabolic reactions.
4. A new, experimental drug is developed that stops ATP from being hydrolyzed to ADP and inorganic phosphate in only *Bacteria* and *Archaea*. Discuss at least two cellular processes that would be affected by inhibiting ATP hydrolysis, and what the outcome would be for *Bacteria* and *Archaea* treated with this drug.

CHAPTER GLOSSARY

Activation energy the energy required to bring the substrate of an enzyme to the reactive state

Anabolic reactions (anabolism) the sum total of all biosynthetic reactions in the cell

Anaerobic respiration a form of respiration in which the terminal electron acceptor is not O_2

ATP (adenosine triphosphate) a nucleotide that is the primary form in which chemical energy is conserved and utilized in cells

ATPase (ATP synthase) a multiprotein enzyme complex embedded in the cytoplasmic membrane that catalyzes the synthesis of ATP coupled to dissipation of the proton motive force

Autotroph an organism capable of biosynthesizing all cell material from CO_2 as the sole carbon source

Calvin cycle the series of biosynthetic reactions by which most phototrophs and most aerobic chemolithotrophs convert CO_2 into organic compounds

Catabolic reactions (catabolism) biochemical reactions leading to energy conservation (usually as ATP) by the cell

Chemolithotroph an organism able to oxidize inorganic compounds (such as H_2 , Fe^{2+} , S^0 , or NH_4^+) as energy sources (electron donors)

Chemoorganotroph an organism that obtains its carbon and reducing power from organic chemicals

Chemotroph an organism that uses chemical reactions as its source of energy

Citric acid cycle (CAC) a cyclical series of reactions resulting in the conversion of acetate to two molecules of CO_2

Coenzyme a small and loosely bound non-protein molecule that participates in a reaction as part of an enzyme

Electron acceptor a substance that can accept electrons from an electron donor, becoming reduced in the process

Electron donor a substance that can donate electrons to an electron acceptor, becoming oxidized in the process

Endergonic a reaction that requires free energy

Enzyme a protein (or in some cases an RNA) catalyst that functions to speed up chemical reactions

Exergonic a reaction that releases free energy

Fermentation anaerobic catabolism in which an organic compound is both an electron donor and an electron acceptor and ATP is produced by substrate-level phosphorylation

Ferredoxin an electron carrier with an extremely electronegative reduction potential

Free energy (G) energy available to do work; $G^{0'}$ is free energy under standard conditions

Glycolysis a biochemical pathway in which glucose is oxidized to pyruvate, which is either used in respiration or fermented (also called the Embden–Meyerhof–Parnas pathway)

Glyoxylate cycle a modification of the citric acid cycle in which isocitrate is cleaved to form succinate and glyoxylate during growth on two-carbon electron donors such as acetate

Heterotroph an organism that uses organic compounds as a carbon source

Nicotinamide adenine dinucleotide (NAD^+/NADH) a cytoplasmic coenzyme that shuttles electrons between various enzymes that catalyze redox reactions

Nitrogenase the enzyme complex required to reduce N_2 to NH_3 in biological nitrogen fixation

Nitrogen fixation the reduction of N_2 to NH_3 by the enzyme nitrogenase

Oxidative phosphorylation the production of ATP from a proton motive force that is formed by electron transport reactions driven by the oxidation of an electron donor and reduction of an external electron acceptor (see also respiration)

Pentose phosphate pathway a series of reactions in which pentoses are catabolized to generate precursors for nucleotide biosynthesis or to synthesize glucose

Photophosphorylation the production of ATP from a proton motive force formed from light-driven electron transport

Phototroph an organism that uses light as its source of energy

Photosynthetic reaction center the site at which light energy is used to excite an electron to a more electronegative state so that it can be donated to the electron transport chain

Proton motive force (pmf) a source of energy resulting from the separation of protons and hydroxyl ions across the

cytoplasmic membrane, generating a membrane electrochemical potential

Redox reaction A chemical reaction in which electrons are transferred between two molecules

Reducing power the ability to donate electrons in metabolic reactions

Reduction potential (E_0') the inherent tendency, measured in volts under standard conditions, of a compound to donate or to accept electrons

Respiration the process in which an electron donor is oxidized and electrons are passed through electron transport reactions to an external electron acceptor in order to generate a proton motive force and synthesize ATP by oxidative phosphorylation

RuBisCO ribulose biphosphate carboxylase, a key enzyme for CO_2 fixation by the Calvin cycle

Substrate-level phosphorylation the production of ATP by the direct transfer of an energy-rich phosphate molecule from a phosphorylated organic compound to ADP

MICROBIOLOGYNOW

Growing Their Own Way

When thinking of microbial growth we typically think of binary fission, the splitting of one cell into two, and indeed this form of growth is common and widespread in the microbial world. But microbial growth takes many different forms. *Streptomyces*, for example, have a complex life cycle, as antibiotic producers often do. *Streptomyces* are common soil bacteria that produce secondary metabolites such as those called *geosmin*, which give soil its characteristic odor. *Streptomyces* also produce a wide range of other secondary metabolites, including many clinically useful antibiotics. Indeed, the antibiotic *streptomycin* provided the first cure for tuberculosis, and its discovery earned the soil microbiologist Selman Waksman a Nobel Prize in 1952. Progress in understanding the *Streptomyces* life cycle is now being made using techniques to grow and image *Streptomyces* in microfluidic chambers.

The life cycle of *Streptomyces* begins with vegetative growth, during which filamentous cells grow by elongating from the tip without cell division. This elongation without division can be visualized (upper image set) in stains where a

red fluorescent protein has been fused to a protein that localizes to the growth tip. Cell division is visualized by a yellow fluorescent protein fused to FtsZ, a protein that mediates septa formation.

Nutrient limitation triggers the formation of aerial hyphae and sporulation. *Streptomyces* sporulation proceeds through multiple fission (lower image set). That is, one filamentous cell divides to form many spores. As seen in the image, many septa are formed simultaneously, resulting in up to 20 spores. Genetic analyses, facilitated by live imaging of growing cells, has revealed that dynamin-like proteins are required during this process. Dynamin is present in eukaryotic cells where it mediates membrane remodeling. This discovery in *Streptomyces* suggests that dynamin-like proteins may have similar functions in bacteria and shows that we still have a lot to learn about microbial growth.

Source: Schlimpert, S., et al. 2017. Two dynamin-like proteins stabilize FtsZ rings during *Streptomyces* sporulation. *Proc. Natl. Acad. Sci. USA* E6176.

In previous chapters we discussed fundamental aspects of microbiology including cell structure and function (Chapter 2) and the principles of microbial metabolism (Chapter 3). In this chapter we explore the areas of microbial growth and cultivation. We will also learn about environmental factors that influence microbial growth and consider some of the major techniques for the control and prevention of microbial growth.

In the first few sections we consider how microbes are grown in laboratory culture and how microbial growth is measured. Recall that when we use the term *microbial growth* we are referring to an increase in population size as the result of cell division (◀ Section 1.2). Culturing microbes and assessing their growth are major events in the daily routine of many microbiologists and microbiology laboratories.

I • Culturing Microbes and Measuring Their Growth

Microorganisms require a suite of nutrients as foodstuffs to produce new microbial cells. Several methods exist for quantifying cell numbers in either natural environments or laboratory cultures.

4.1 Feeding the Microbe: Cell Nutrition

Because the metabolic capacities of microbes differ, their nutrient requirements also differ. However, all microbes require a core set of nutrients. Some nutrients, called *macronutrients*, are required in large amounts, while others, called *micronutrients*, are required in minute amounts. We begin by dissecting the cell to reveal its chemical composition and then consider the nutrients that all cells require.

Chemical Makeup of a Cell

A single cell of *Escherichia coli* weighs, on average, just about 10^{-12} g, and over 75% of that mass is water. However, when considering the composition of cells, it is typical to refer to cell dry weight, which for *E. coli* is about 184×10^{-15} g (184 fg) per cell. Just a handful of the chemical elements predominate in living systems. The elements carbon (C), oxygen (O), nitrogen (N), hydrogen (H), phosphorus (P), and sulfur (S) account for about 96% of the dry weight of an average bacterial cell (Figure 4.1), and these six elements are universally required by all life forms. The next 3.7% of a cell's mass is composed of potassium (K), sodium (Na), calcium (Ca), magnesium

(Mg), chlorine (Cl), and iron (Fe) (Figure 4.1c), and these elements are required by most (but not all) microorganisms. In addition, at least another 20 elements can be found in cells of *E. coli* (Figure 4.1a) and in cells across the three domains of life. In total, microbes can metabolize 62 different elements in one way or another (Figure 4.1a).

Cells are comprised mostly of macromolecules, including proteins, lipids, polysaccharides, lipopolysaccharides, and nucleic acids, which together comprise more than 96% of the dry weight of an *E. coli* cell (Figure 4.1b). The vast majority of these are proteins and RNAs (Figure 4.1b). Interestingly, as important as DNA is to a cell (the cell genome), it contributes a very small percentage of a cell's dry weight (Figure 4.1b).

Carbon, Nitrogen, and Other Macronutrients

Carbon and nitrogen are present in large amounts in all cells. Heterotrophs (organisms that require organic carbon) obtain carbon from the breakdown of organic polymers or from the direct uptake of their monomeric constituents: the amino acids, fatty acids, organic acids, sugars, nitrogen bases, and other organic compounds. Some microbes are autotrophs and can synthesize organic compounds from carbon dioxide (CO₂). The bulk of nitrogen in nature

Figure 4.1 Elemental and macromolecular composition of a bacterial cell. (a) A microbial periodic table of the elements. With the exception of those shown in row 7, other elements in row 7 and elements in rows beyond row 7 are not known to be metabolized. (b) Relative abundance of macromolecules in a bacterial cell. Data from *Escherichia coli* and *Salmonella typhimurium*: *Cellular and Molecular Biology*. ASM, Washington, DC (1996). (c) Distribution of the elements in an average *E. coli* cell (dry weight). "Other" includes in order of abundance: Se, B, Cu, Mn, Zn, F, Si, As, Cs, Sr, Ba, V, Co, W, and Ni.

exists in proteins, ammonia (NH_3), nitrate (NO_3^-), or nitrogen gas (N_2). Virtually all microorganisms can use NH_3 as their nitrogen source and many can also use nitrate (NO_3^-). Some microbes can use organic nitrogen sources, such as amino acids, and a few can use N_2 (the nitrogen-fixing bacteria).

In addition to C and N (and O and H from H_2O), many other macronutrients are needed by cells but typically in smaller amounts (Figure 4.1c). Phosphorus is required for nucleic acids and phospholipids and is usually assimilated by microbes as inorganic phosphate (PO_4^{3-}). Sulfur is present in the amino acids cysteine and methionine and also in several vitamins, including thiamine, biotin, and lipoic acid. Most microbes can assimilate inorganic forms of S such as sulfate (SO_4^{2-}) or sulfide (H_2S) while others assimilate S from organic sulfur compounds. Potassium (K) is required for the activity of several enzymes, whereas magnesium (Mg) stabilizes ribosomes, membranes, and nucleic acids and is also required for the activity of many enzymes. Calcium (Ca) and sodium (Na) are essential nutrients for only a few organisms. For example, most marine organisms have a strict requirement for NaCl.

Micronutrients: Trace Metals and Growth Factors

Many enzymes require a metal ion or small organic molecule as a cofactor in order to catalyze their specific reaction (◀ Section 3.5). For this reason, the growth of microorganisms requires various metals, and chief among these is iron (Fe). Iron is present in cytochromes and several other enzymes that play major roles in cellular respiration or related oxidation–reduction reactions. Besides iron, many other metals may be required or otherwise metabolized by microorganisms (Figure 4.1a). Collectively these metals are called *trace metals* because

they are required in such small amounts. Table 4.1 lists the major trace metals and other trace elements of life and examples of enzymes or other molecules in which each is found. Enzymes with a trace metal requirement may be synthesized by the cell but will not function properly if the cell is starved for these metals.

Growth factors differ from trace metals in that they are *organic* micronutrients rather than metals (Table 4.1). Vitamins, which typically function as coenzymes (◀ Section 3.5), are the most frequently required growth factors, and a few common ones are shown in Table 4.1. While some microbes are able to biosynthesize all of their own growth factors, many organisms (including animals) need to assimilate diverse growth factors from the environments (or from their diet). Besides vitamins, other common growth factors can include amino acids, purines, pyrimidines, and several other organic molecules.

Growth factor requirements vary widely among microorganisms. For example, cyanobacteria are autotrophic microbes that inhabit aquatic environments such as lakes and oceans; they can synthesize all of their own growth factors and need little if any supplementation. By contrast, the lactic acid bacteria *Streptococcus*, *Lactobacillus*, and *Leuconostoc* inhabit environments rich in nutrients, such as certain foods and in the guts of animals (▶ Sections 16.6 and 24.2), and as a result have evolved to rely on their organic-rich environments for these required nutrients.

If a cell is to grow and divide, it must take up macronutrients and micronutrients from the environment and transform them into new cell material. Hence, to grow microbes in the laboratory, we need to satisfy their growth requirements. If the nutrients, trace metals, and growth factors that a microbe needs are not made available to it, the organism will not grow. In the next section we consider how these

TABLE 4.1 Micronutrients needed by microorganisms^a

I. Trace elements		II. Growth factors	
Element	Function	Growth factor	Function
Boron (B)	Autoinducer for quorum sensing in bacteria; also found in some polyketide antibiotics	PABA (<i>p</i> -aminobenzoic acid)	Precursor of folic acid
Cobalt (Co)	Vitamin B ₁₂ ; transcarboxylase (only in propionic acid bacteria)	Folic acid	One-carbon metabolism; methyl transfers
Copper (Cu)	In respiration, cytochrome <i>c</i> oxidase; in photosynthesis, plastocyanin, some superoxide dismutases	Biotin	Fatty acid biosynthesis; some CO ₂ fixation reactions
Iron (Fe) ^b	Cytochromes; catalases; peroxidases; iron–sulfur proteins; oxygenases; all nitrogenases	B ₁₂ (Cobalamin)	One-carbon metabolism; synthesis of deoxyribose
Manganese (Mn)	Activator of many enzymes; component of certain superoxide dismutases and of the water-splitting enzyme in oxygenic phototrophs (photosystem II)	B ₁ (Thiamine)	Decarboxylation reactions
Molybdenum (Mo)	Certain flavin-containing enzymes; some nitrogenases, nitrate reductases, sulfite oxidases, DMSO–TMAO reductases; some formate dehydrogenases	B ₆ (Pyridoxine)	Amino acid/keto acid transformations
Nickel (Ni)	Most hydrogenases; coenzyme F ₄₃₀ of methanogens; carbon monoxide dehydrogenase; urease	Nicotinic acid (Niacin)	Precursor of NAD ⁺
Selenium (Se)	Formate dehydrogenase; some hydrogenases; the amino acid selenocysteine	Riboflavin	Precursor of FMN, FAD
Tungsten (W)	Some formate dehydrogenases; oxotransferases of hyperthermophiles	Pantothenic acid	Precursor of coenzyme A
Vanadium (V)	Vanadium nitrogenase; bromoperoxidase	Lipoic acid	Decarboxylation of pyruvate and α-ketoglutarate
Zinc (Zn)	Carbonic anhydrase; nucleic acid polymerases; many DNA-binding proteins	Vitamin K	Electron transport
		Coenzymes M and B	Methanogenesis ^c
		F ₄₂₀ and F ₄₃₀	Methanogenesis ^c

^aNot all trace elements or growth factors are needed by all organisms, and many growth factors are biosynthesized and not required from the environment.

- Which two classes of macromolecules contain most of a cell's nitrogen?
- Differentiate between trace metals and growth factors. How are these used by the cell?

4.2 Growth Media and Laboratory Culture

Laboratory cultures of microorganisms are grown in **culture media** (singular, medium), nutrient solutions tailored to the particular organism to be grown (◀ Section 1.13). Because laboratory culture of a microbe is required for its detailed study, careful attention must be paid to the selection and preparation of media for laboratory culture to be successful. Culture media must be sterilized before use, and sterilization is typically achieved by heating the medium under pressure in an *autoclave*. We discuss the operation and principles of the autoclave in Section 4.17, along with other methods for sterilizing culture media and laboratory utensils and other devices.

Classes of Culture Media

Although thousands of recipes for microbial culture media exist, two broad classes of culture media are widely used in microbiology:

defined media and *complex media*. **Defined media** are prepared by adding precise amounts of pure inorganic or organic chemicals to distilled water. Therefore, the *exact composition* of a defined medium (in both a qualitative and quantitative sense) is known. Of major importance in any culture medium is the carbon source because all cells need large amounts of carbon to make new cell material (Figure 4.1). The particular carbon source and its concentration depend on the organism to be cultured. **Table 4.2** lists recipes for four different culture media. Some defined media, such as the one listed for *Escherichia coli*, are considered “simple” because they contain only a single carbon source. In such a medium, *E. coli* biosynthesizes all of its cellular materials from glucose.

For culturing many microorganisms, knowledge of the exact composition of a medium is not essential. In these instances, complex media may suffice and may even be advantageous. **Complex media** are made from digests of microbial, animal, or plant products, such as milk protein (casein), beef (beef extract), soybeans (tryptic soy broth), yeast cells (yeast extract), or any of a number of other highly nutritious substances (Table 4.2). For example, the media originally used by Pasteur in his classic early studies in microbiology were complex media containing yeast extract (◀ Section 1.11). Such digests are commercially available in dehydrated form and need only be hydrated with distilled water to form a culture medium. However, the disadvantage of a complex medium is that its exact nutritional composition is unknown.

Culture media are sometimes prepared that are selective or differential (or both), especially media used in medical microbiology. A *selective medium* contains compounds that inhibit the growth of

TABLE 4.2 Examples of culture media for microorganisms with simple and demanding nutritional requirements ^a

some microorganisms but not others. Selective media are commercially available for the isolation of certain common gut pathogens, such as the enteric bacteria *Salmonella* or those strains of *E. coli* that cause foodborne illnesses. For example, bile salts are often added to culture media for the selective isolation of these bacteria because bile salts kill many bacteria that are unable to grow in the gut. A *differential medium* is one to which an indicator (typically a dye) is added, which reveals by a color change whether a particular metabolic reaction has occurred during growth. For example, the detection of lactic acid bacteria, which secrete lactic acid and cause the pH to drop, can be facilitated by incorporating a pH-sensitive dye into the culture medium that changes color when conditions become acidic. Differential media are useful for distinguishing bacteria and are widely used in clinical diagnostic microbiology and in microbial taxonomy. Differential and selective media are discussed in a clinical microbiology context in Chapter 29.

Nutritional Requirements and Biosynthetic Capacity

Of the four culture medium recipes in Table 4.2, three are defined and one is complex. The complex medium, which is rich in nutrients, is easiest to prepare and it supports growth of both *Escherichia coli* (a common enteric bacterium) and *Leuconostoc mesenteroides* (a lactic acid bacterium often associated with fermented foods), the examples used in Table 4.2. By contrast, only *E. coli* grows in the simple defined medium because *L. mesenteroides* has more nutritional requirements (it requires more growth factors) than *E. coli*. The nutritional needs of *L. mesenteroides* can be satisfied by preparing either a highly supplemented defined medium, a laborious undertaking because of all the individual nutrients that need to be added (Table 4.2), or by preparing a complex medium, a much easier and quicker operation.

The fourth medium listed in Table 4.2 supports growth of the bacterium *Thiobacillus thioparus*, an aerobic sulfur-oxidizing chemolithotroph (◀ Section 3.11). *T. thioparus* derives all of its carbon from CO_2 (that is, it is autotrophic) and conserves energy from the oxidation of sulfur compounds such as thiosulfate ($\text{Na}_2\text{S}_2\text{O}_3$). *T. thioparus* is common in low-nutrient sulfur-rich environments where it only has access to inorganic nutrients. Thus, *T. thioparus* has evolved to biosynthesize all of its needed growth factors and does not require organic nutrients of any type.

The take-home lesson from Table 4.2 is that different microorganisms may have vastly different nutritional requirements. For successful cultivation, it is necessary to understand an organism's physiology and nutritional requirements and then supply it with the nutrients it needs in both the proper form and amount.

Laboratory Culture

Laboratory media can be either liquid (Table 4.2) or solid (Figure 4.2). Culture media are solidified with *agar*, an algal polysaccharide first

Figure 4.2 Bacterial colonies. Colonies are visible masses of cells formed from the division of one or a few cells and can contain over a billion (10^9) individual cells. (a) *Serratia marcescens*, grown on MacConkey agar. (b) Close-up of colonies outlined in part a. (c) *Pseudomonas aeruginosa*, grown on trypticase soy agar. used in the classical studies of Robert Koch (◀ Section 1.12). Solid media immobilize cells so that as they grow, they accumulate in a pile to form visible, isolated cell masses called *colonies* (Figure 4.2). Microbial colonies vary in shape, color, texture, and size depending on the organism, the culture conditions, the nutrient supply, and other physiological parameters. Colony appearance is consistent for a given organism on a particular type of medium. Hence, **colony morphology**—the visible characteristics of a colony—can sometimes be used to identify microorganisms but is used routinely to determine if a culture is pure (only one microbe is present), contaminated (undesired organisms co-occur with a desired organism), or mixed (many microbes are present). Plates inoculated from a mixed culture (such as a natural sample, Figure 4.2e) or from a

contaminated pure culture will typically contain more than one colony type.

Propagation of microbial cultures requires **aseptic technique** (Figure 4.3), a series of steps by which microbes are transferred between growth media without contamination. Contamination can be introduced from microbes in the air, in liquid droplets, or on surfaces. With liquid medium, the goal is to transfer a microbial culture while protecting the culture vessel from air currents or contact with nonsterile surfaces (Figure 4.3a). With agar plates, the plan is basically the same but with a greater emphasis on keeping the surface of the agar protected from aerosols or particulate matter in air (Figure 4.3b). A mastery of aseptic technique is required for maintaining pure cultures, as airborne contaminants are virtually

The plate cover is opened just enough to permit streaking manipulations. In streaking a plate, the microbial cells are separated by the streaking process to yield widely separated single cells that then grow and divide to form colonies.

everywhere, even in what may appear to be a very clean microbiology laboratory.

The primary method for obtaining *pure cultures* that contain a single microbe, and of verifying culture purity, is to perform the *streak plate* technique (Figure 4.3b). In this method, an *inoculating loop* is used to spread a sample across a solidified medium on an agar plate. Any microbes that are able to grow will form colonies, and colony morphology can be examined to determine the number and type of microbes present.

Many techniques for obtaining pure cultures have been developed, and some of the more common ones will be discussed in Chapter 19. But for now, we turn our attention away from general methods of culturing microbes to explore methods for quantifying their growth.

Check Your Understanding

- What is meant by the word sterile? Why is aseptic technique necessary for successful maintenance of pure cultures in the laboratory?
- How many *E. coli* cells would be present in a single bacterial colony whose dry weight was 0.2 mg?

4.3 Microscopic Counts of Microbial Cell Numbers

Assessing cell numbers gives quantitative information on the state of a laboratory microbial culture or a microbial community in nature. Several methods for enumerating a microbial population have been developed, each having their own strengths and caveats. We begin with the classic “total count” carried out by microscopic examination of a culture or natural sample.

Total Cell Count

Total counts of microbial numbers in a culture or natural sample can be done by simply observing and enumerating the cells present by a *microscopic cell count*. Microscopic counts can be performed either on samples dried on slides or on liquid samples. Dried

samples can be stained to increase contrast between cells and their background (◀ Section 1.8) when observed by bright-field microscopy, but a phase-contrast microscope is essential for observing unstained preparations. With liquid samples, counting chambers consisting of a grid with squares of known area etched on the surface of a glass slide are used (Figure 4.4). When the coverslip is placed on the chamber, each square on the grid has a precise volume. The number of cells per unit area of grid can be counted under the microscope, giving a measure of the number of cells per small chamber volume. The number of cells per milliliter of suspension is calculated by employing a conversion factor based on the volume of the chamber sample (Figure 4.4).

Microscopic counting is a quick and easy way of estimating microbial cell numbers. However, it has several limitations that restrict its usefulness. For example, without special staining techniques, dead cells cannot be distinguished from live cells, and precision is difficult to achieve, even when replicate counts are made. Moreover, small cells are often difficult to see under the microscope, which can lead to erroneous counts, and cell suspensions of low density (less than about 10^6 cells/milliliter) will have few if any cells in a microscope field unless the sample is first concentrated and resuspended in a small volume. Finally, motile cells must be killed (usually with formaldehyde) or otherwise immobilized before counting, and debris in the sample may easily be mistaken for microbial cells.

Microscopic Cell Counts in Microbial Ecology

Despite the many potential caveats, microbial ecologists often use microscopic cell counts on natural samples. But they do so by using stains to visualize the cells, often stains that yield phylogenetic or other key information about the cells, such as their metabolic properties (▶ Section 19.5).

Many fluorescing stains can be used in a general way. For example, the stain DAPI (◀ Section 1.8 and Figure 1.25e) stains all cells because it binds tightly to DNA. Other general fluorescent stains can differentiate live from dead cells by detecting whether a cell’s cytoplasmic membrane is intact or not. By contrast, fluorescent stains that are highly specific for certain organisms or groups of related organisms can be prepared by attaching fluorescent dyes to specific nucleic acid probes. For example, *phylogenetic stains* that stain only species of *Bacteria* or only species of *Archaea* can be used in combination with

Figure 4.4 Direct microscopic counting procedure using the Petroff–Hausser counting chamber. A phase-contrast microscope is typically used to count the cells to avoid the necessity for staining.

nonspecific stains to determine the proportion of each domain present in a sample (► Section 19.5). Other fluorescent probes have been developed that target genes encoding enzymes that catalyze specific metabolic processes; if a cell is stained by one of these probes, a metabolism can be inferred that may reveal the cell's ecological role in the microbial community. In all of these cases, if cells in the sample are present in only low numbers, for example in a sample of ocean water, this limitation can be overcome by first concentrating the cells on a filter and then counting them after staining.

Because they are easy to do and often yield useful baseline information, microscopic cell counts are common in ecological studies of natural microbial environments. We pursue this theme in more detail in Chapter 19. In the next section we consider quantifying microbes using growth-based methods.

Check Your Understanding

- What are some of the problems that can arise when unstained preparations are enumerated in microscopic counts?
- Using microscopic techniques, how might you determine the number of *Archaea* present in an alpine lake?

4.4 Viable Counting of Microbial Cell Numbers

A **viable** cell is one that is alive and able to grow. Some viable microbes are able to grow on laboratory culture media; thus, while microscopic counts often fail to distinguish viable microbes from dead microbes, we can use culture media to perform viable counts. A **viable count** is performed by spreading microbes on solid media and counting colonies, and hence is often called a **plate count** because

agar plates are required. The assumption made in a viable count is that each viable cell will grow and divide to yield a single colony, and hence, colony numbers are taken as a measure of cell numbers.

Methods for Viable Counts

There are at least two ways of performing a plate count: the *spread-plate* method and the *pour-plate* method (Figure 4.5). In the spread-plate method, a volume (usually 0.1 ml or less) of an appropriately diluted culture is spread over the surface of an agar plate using a sterile glass spreader. In the pour-plate method, a known volume (usually 0.1–1.0 ml) of culture is pipetted into an empty sterile Petri plate. Molten agar medium, tempered to just above gelling temperature (50°C), is then added and gently mixed before allowing the agar to solidify.

With both the spread-plate and pour-plate methods, it is important that the number of colonies developing on or in the medium not be too many or too few. On crowded plates some cells may not form colonies, and some colonies may fuse, leading to erroneous measurements. If the number of colonies is too small, the statistical significance of the calculated count will be low. The usual practice, which is most valid statistically, is to count colonies only on plates that contain between 30 and 300 colonies.

A major assumption of the viable plate count technique is that one cell forms one colony. However, we have already learned that some bacteria are filamentous and many form clusters or sticky biofilms (Chapter 1). For example, a bacterial filament might contain 10 or more cells, but since these cells are firmly attached together, such a filament would form only one colony. Hence, data from viable counts are typically expressed as the number of *colony-forming units* (CFU) obtained rather than the actual number of viable cells, to account for clumps containing more than one viable cell.

Spread-plate method

Pour-plate method

Figure 4.5 Two methods for the viable count. Only surface colonies form in the spread plate technique. By contrast, in the pour-plate method, colonies form within the agar as well as on the agar surface. On the far right are photos of colonies of *Escherichia coli* formed from cells plated by the spread-plate method (top) or the pour-plate method (bottom).

Diluting a Sample

Samples often contain thousands, millions, or even billions of viable bacteria, and so samples must typically be diluted to obtain a suspension that will yield a countable number of colonies. A series of 10-fold dilutions are commonly used prior to performing viable plate counts (Figure 4.6). To make a 10-fold dilution, 1 ml of sample can be added to 9 ml of diluent (usually water, a dilute salts solution, or growth medium). In this way, one milliliter of this 10-fold dilution contains 0.1 ml (10^{-1} ml) of the original sample and 0.9 ml of diluent.

With dense cultures, several *serial* dilutions are needed to yield a countable number of colonies (Figure 4.6). For example, if a sample is suspected to contain more than 10^5 cells then the sample can be diluted 1000-fold by performing three successive 10-fold dilutions ($1/10 \times 1/10 \times 1/10 = 1/1000$). In this way, one milliliter of a 1000-fold dilution contains 0.001 ml (10^{-3} ml) of sample and 0.999 ml of diluent. To determine the number of cells in the sample, the number of colonies observed is divided by the amount of sample plated. Hence, if 1 ml of a 1000-fold dilution is plated, this is equivalent to plating 0.001 ml of the original sample. If 159 colonies form from this sample, the original sample must have contained 159×10^3 (which is equivalent to 1.59×10^5) CFU (Figure 4.6). Because the number of bacteria in a sample is often not known

Figure 4.6 Procedure for viable counting using serial dilutions of the sample and the pour-plate method. The sterile liquid used for making dilutions can simply be water, but a solution of mineral salts or actual growth medium may yield a higher recovery. The dilution factor is the reciprocal of the dilution.

ahead of time, it is usually necessary to make multiple dilutions to ensure a countable number of colonies (Figure 4.6).

Applications of the Plate Count

Despite the caveats associated with viable counting, the procedure is quick and easy to do and so is widely used in microbiology. For example, in food, dairy, medical, and aquatic microbiology, viable counts are employed routinely. The method has the virtue of high sensitivity, because as few as one viable cell per sample plated can be detected. This feature allows for the sensitive detection of microbial contamination of foods or other materials.

The use of highly selective culture media and growth conditions allows the plate count to be used to target particular species in a sample containing many organisms. For example, a complex medium containing 10% NaCl is very useful in isolating species of potentially pathogenic *Staphylococcus* from skin, because the salt inhibits growth of most other skin bacteria. In practical applications such as in the food industry, viable counting performed using both a complex medium and a selective medium on the same sample allows for simultaneous quantitative and qualitative assessments of food quality and safety. That is, with a single food sample, the complex medium yields a total cell count—a relative indicator of freshness and shelf life—while the selective medium indicates the presence or absence of a particular pathogen that may be transmitted in the food.

Targeted counting is also common in wastewater and other water analyses. For instance, enteric bacteria such as *Escherichia coli* originate from feces and are easy to recover from natural samples using selective media; if enteric bacteria are detected in a water sample from a swimming site, for example, their presence is a signal that the water contains fecal matter and is therefore unsafe for human contact.

Caveats to Plate-Counting Methods

Direct microscopic counts of natural samples typically reveal far more microbes than are recoverable on any single culture medium. Thus, although a very sensitive technique, plate counts can be highly unreliable when used to assess total cell numbers of natural samples, such as soil and water. In microbiology, this has been referred to as the *great plate count anomaly*.

Why do plate counts reveal lower numbers of cells than direct microscopic counts? The reason is that different organisms, even those present in a very small natural sample, have vastly different requirements for nutrients and growth conditions in laboratory culture (Sections 4.1 and 4.2 and Table 4.2). Thus, one medium and set of growth conditions can only be expected to support the growth of one subset of the total microbial community. For example, if a sample has 10^9 viable cells but only 10^6 them are capable of growing on a given culture medium, then the viable plate count will miss 99.9% of the viable cell population, a vast underestimation of the actual number of organisms present in the sample.

Plate count results thus carry a large caveat. Plate counts targeted to specific organisms using highly selective media (Section 4.2), as in, for example, the microbial analysis of sewage or food, can often yield quite reliable data, since the physiology of the targeted organisms is known and so the recovery of viable cells is near 100%. By contrast, “total” cell counts of the same samples using a single medium and set of growth conditions may be, and usually are,

underestimates of actual cell numbers by one to several orders of magnitude. Because of this problem, a wide variety of molecular methods have been developed to detect and quantify specific organisms in natural samples without the need for cultivating them in the laboratory. We explore these methods and the important information they can reveal in Chapter 19.

Check Your Understanding

- Describe how you would dilute a bacterial culture by 10^{-7} .
- Explain the “great plate count anomaly.”

4.5 Turbidimetric Measures of Microbial Cell Numbers

Though small, microbial cells are large enough to scatter light, and the amount of light scattered in a cell suspension is proportional to the number of cells present. A cell suspension looks cloudy (turbid)

to the eye because cells scatter light that passes through the suspension. The more cells that are present, the more light is scattered, and hence the more turbid the suspension. Hence, *turbidity* measurements offer a rapid and widely used approach to estimating cell numbers in a solution.

Optical Density and Its Relationship to Cell Numbers

Turbidity is measured with a *spectrophotometer*, an instrument that measures the unscattered light that passes through a sample (Figure 4.7). A spectrophotometer employs a prism or diffraction grating to generate incident light of a specific wavelength (Figure 4.7a). Commonly used wavelengths for microbial turbidity measurements include 480 nm (blue), 540 nm (green), and 660 nm (red). Sensitivity is best at shorter wavelengths, but measurements of dense cell suspensions are more accurate at longer wavelengths.

The unit of turbidity is *optical density* (OD) at the wavelength specified, for example, OD_{540} for measurements at 540 nm (Figure 4.7). For unicellular organisms, optical density is proportional, within certain limits, to cell number. Turbidity readings can therefore be used as a substitute for total or viable counting methods. However, before this can be done, a standard curve must be prepared that

Figure 4.7 Turbidity measurements of microbial growth. (a) Measurements of turbidity are made in a spectrophotometer. The photocell measures incident light unscattered by cells in suspension and gives readings in optical density units. (b) Liquid cultures of *Escherichia coli*; the tube on the far left is sterile medium.

The increasing (left to right) optical density (OD_{540}) of each culture is shown below the tube, as is the actual cell number measured in a viable count. (c) Typical growth curve data for two organisms growing at different growth rates. For practice, calculate the generation time of the two cultures using the formula

$n = 3.3 (\log N_t - \log N_0)$ where N_t and N_0 are two different OD readings with a time interval t between the two (see Section 4.7). Which organism is growing faster, A or B? (d) Relationship between cell number and turbidity readings. Note that the direct relationship between these values breaks down at high turbidities.

relates cell number (microscopic or viable count) to turbidity. As can be seen in such a plot, proportionality only holds within limits (Figure 4.7d). At high cell densities, light scattered away from the spectrophotometer's photocell by one cell can be scattered back toward the photocell by another, and as a result, the one-to-one correspondence between cell number and turbidity deviates from linearity. Nevertheless, when a standard has been prepared, turbidimetric estimates of bacterial numbers are very useful.

Other Issues with Turbidimetric Growth Estimates

On the one hand, turbidity measurements are quick and easy to perform and can be made without destroying or significantly disturbing the sample. For these reasons, turbidity measurements are widely employed to monitor growth of pure cultures of *Bacteria* and *Archaea* and can also be used with many microbial eukaryotes. With turbidimetric assays, the same sample can be checked repeatedly over time and the measurements plotted on a semilogarithmic plot versus time (Figure 4.7c) to measure growth of a microorganism over time.

On the other hand, turbidity measurements can occasionally be problematic. Although many microorganisms grow evenly distributed in suspensions in liquid medium, many do not. Some bacteria routinely form small to large clumps, and in such instances, OD measurements may be quite inaccurate as a measure of total microbial mass. In addition, many bacteria form biofilms on the sides of tubes or other growth vessels. Hence for OD measurements to be an accurate reflection of cell mass (and thus cell numbers) in a liquid culture, clumping and biofilms have to be minimized. This can be accomplished by stirring, shaking, or in some way keeping the cells well mixed during the growth process to prevent the formation of cell aggregates and the sticking of swimming cells to surfaces. Some bacteria are just naturally planktonic and stay well suspended in liquid medium for long periods. But if a solid surface is available, most bacteria will eventually develop a static biofilm, and accurately quantifying cell numbers by turbidity in such a case can be difficult or even impossible.

Check Your Understanding

- List two advantages of using turbidity as a measure of cell growth.
- Describe how you could use a turbidity measurement to tell how many colonies you would expect from plating a culture of a given OD.

II • Dynamics of Microbial Growth

Microorganisms that divide by binary fission grow at exponential rates into cell populations whose numbers over time are predictable from simple mathematical models. A few microbes grow by budding, and some can form sticky cell masses called biofilms.

In Part II of this chapter we consider the actual process of microbial growth. Here we consider the different ways in which microbes grow, explore the basic quantitative relationships displayed by

growing microbial cultures, and introduce an important laboratory tool—the chemostat—for manipulating exponentially growing microbial cultures to better answer specific questions.

4.6 Binary Fission and the Microbial Growth Cycle

Growth is the result of cell division and is the ultimate process in the life of a microbial cell. In microbiology, growth is defined as *an increase in the number of cells*. As macromolecules accumulate in the cytoplasm of a cell, they assemble into major cell structures, such as the cell envelope, cytoplasmic membrane, ribosomes, and so on, eventually leading to cell division. In a growing culture of a rod-shaped bacterium such as *Escherichia coli*, cells elongate to approximately twice their original length and then form a partition that constricts the cell into two identical daughter cells (Figure 4.8). This process is called **binary fission** (“binary” to indicate that two cells have arisen from one).

The partition that forms between dividing cells is called a *septum* and results from the inward growth of the cell envelope from opposing directions; septum formation continues until the two daughter cells are pinched off. There are some variations in this general pattern of binary fission. In some bacteria, such as *Bacillus subtilis*, a septum forms without cell wall constriction (Figure 4.9), while in the budding bacterium *Caulobacter* (◀ Figure 2.14a, and see Figure 4.18) constriction occurs but no septum is formed.

When one cell eventually separates to form two cells (Figure 4.8), we say that *one generation* has occurred, and the time required for this process is called the **generation time** (or *doubling time*). Each daughter cell is essentially identical, having received a copy of the chromosome(s) and sufficient copies of all cellular materials required to begin life as an independent entity. Microbes differ in their doubling times, and the doubling time of any given microbe varies depending on growth conditions. Under optimal growth conditions, the generation time of *E. coli* is about 20 min. The fastest-growing

Figure 4.8 Binary fission in a rod-shaped bacterium. Cell numbers (and all components of the cells) double every generation.

(b) The green fluorescent protein lights up entire cells. (c) A dye that stains only the cytoplasmic membrane shows that septa contain membrane (and cell wall) material.

microbes known can double in less than 10 minutes while the slowest can have generation times of several months or even longer.

The Microbial Growth Cycle

Under optimal conditions, growth by binary fission can cause a rapid increase in the number of cells present, but conditions are rarely optimal, even in laboratory culture. Typically, microbes are grown in **batch culture**, which describes the growth of microbes in a fixed volume of liquid enclosed within a container such as a test tube or a flask. The nutrients in such a culture flask are finite and cannot support growth indefinitely. Hence, in batch culture microbes typically exhibit a growth cycle called the microbial **growth curve** (Figure 4.10). The growth curve is composed of four phases: lag phase, exponential phase, stationary phase, and decline phase.

Lag and Exponential Phases

When a microbial culture is inoculated into fresh growth media (Section 4.2), there is typically an initial pause during which the

cells do not grow. This period between inoculation and the onset of growth is called the **lag phase** (Figure 4.10). Microbes exhibit a lag phase because transfer to fresh medium represents new environmental conditions for the cells, which need to alter their metabolic state to respond to these new conditions.

The lag phase may be brief or extended depending on the previous history of the cells (old culture, young culture, type of growth medium, and so on), the choice of growth medium, and the growth conditions. For example, if an actively growing culture is transferred into a new flask containing the same type of medium under the same growth conditions, there will be very little lag. This is because the cell needs to make very few metabolic adjustments to this new condition. However, if the inoculum is from an old culture, there is usually a longer lag because cell viability may be low, or the cells may need to synthesize many enzymes and macromolecules before they can begin growing. A long lag is also observed when a microbial culture is transferred from a nutrient-rich to a nutrient-poor culture medium. In order to grow, cells must have a complete set of enzymes to biosynthesize the essential metabolites absent from the nutrient-poor medium. The more enzymes and molecules that a cell must manufacture in order to grow in a new environment, the longer the lag.

The **exponential phase** of growth is the period when the growing cell population doubles at regular intervals (Figure 4.10). This phase is also called *balanced growth* because cells are as close to being metabolically identical throughout this period as they can be. Hence, in order to minimize experimental variation, most experiments are performed with microbes taken from cultures in the exponential phase of growth. Rates of exponential growth vary greatly and are influenced by choice of media, growth conditions, and the organism itself. Exponential growth continues until conditions in the batch culture can no longer sustain growth.

Stationary and Death Phases

In a batch culture, exponential growth cannot continue forever. Consider the fact that a single cell weighing one-trillionth (10^{-12}) of a gram that doubled unabated every 20 min for 48 hours would produce a population of cells that weighed 4000 times more than planet Earth. Obviously, this is impossible because the carrying capacity of an environment will always limit growth of the organisms within it. In the case of batch cultures, growth is limited because of either nutrient depletion or the accumulation of microbial waste products. When exponential growth ceases for one (or both) of these reasons, the population enters *stationary phase* (Figure 4.10).

In **stationary phase**, there is no net increase or decrease in cell number and thus the growth rate of the population is zero. During stationary phase, cellular metabolism shifts away from growth as the cell prepares for maintenance and survival. Despite

Figure 4.10 Typical growth curve for a bacterial population. A viable count measures the cells in the culture that are capable of reproducing. Optical density (turbidity), a quantitative measure of light scattering by a liquid culture (see Figure 4.7), increases with the increase in cell number.

growth arrest, energy metabolism and biosynthetic processes in stationary phase cells may continue, but typically at a greatly reduced rate. Eventually, the population will enter the **decline phase** of the growth cycle as the total number of cells decreases due to cell death. Cell division may still occur for some cells in the population during the stationary and decline phases, but this meager increase in number is balanced by the death of other cells. Some microbial cultures exhibit *cryptic growth* during stationary and decline phases as subpopulations of cells adapt to cannibalize and reuse resources released from dying cells. Also, if a culture is prevented from drying, some number of cells may remain for months or even years.

We now consider how exponential growth can be put on a quantitative footing using some basic mathematical relationships and how these relationships can be exploited in laboratory studies of growing microbial cultures.

Check Your Understanding

- Under what conditions would a lag phase not occur?
- Why do cells enter stationary phase?
- Define the term generation. What is meant by the term generation time?

4.7 Quantitative Aspects of Microbial Growth

During cell division, one cell becomes two. During that doubling time (the generation time), both the total cell *number* and cell *mass* double (Figure 4.8). As we will see, cell numbers in a bacterial culture can quickly become very large, and so it is necessary to deal with the topic of microbial growth using quantitative methods.

Plotting Growth Data

Exponential growth of a population occurs during a period when cell number doubles at regular intervals (defined as the doubling or generation time, Section 4.6). For example, consider a single cell that initiates exponential growth with a generation time of 30 minutes (Figure 4.11). When we plot the change in cell number over time on arithmetic (linear) coordinates, we obtain an upwardly sweeping curve with a continuously increasing slope (Figure 4.11b). By contrast, when the cell number is plotted on a logarithmic ($\log_{10}$) scale as a function of time (a *semilogarithmic* graph) the points fall on a straight line (Figure 4.11b). This straight-line function reflects the fact that the cells are growing exponentially and that the population is doubling in a constant time interval.

Semilogarithmic graphs are also convenient for estimating the generation time of a culture from actual growth data, since generation times can be inferred directly from the graph as shown in Figure 4.12. For example, the generation time can be determined by finding the time it takes for the number of cells to double (Figure 4.12). In a more formal sense, we define generation time (g) as the time (t) per generation (n), which is $g = t/n$. Hence, a population that takes six hours ($t = 6$ h) to double once ($n = 1$) has a generation time of 6 h (Figure 4.12a). Several of the terms and expressions useful in quantifying microbial growth are defined in Figure 4.12c.

Time (h)	Generation number (n)	Total number of cells
0	0	1
0.5	1	2
1	2	4
1.5	3	8
2	4	16
2.5	5	32
3	6	64
3.5	7	128
4	8	256
4.5	9	512
5	10	1024

(a)

(b)

The Mathematics of Bacterial Growth

Starting with a single cell and considering the fact that the cell number of an exponentially growing culture doubles every generation, the number of cells present at generation n can be expressed as 2^n . For example, after 3 generations there will be $2^3 = 8$ cells, after 10 generations there will be $2^{10} = 1024$ cells, and so on (Figure 4.11a). If exponential growth began with two cells instead of one, the number of cells at any generation would be doubled (for example, $2 \times 2^{10} = 2048$ cells), and if we started with three cells, the number of cells at any generation would be tripled ($3 \times 2^{10} = 3072$ cells). Hence, it is possible to calculate the number of cells (N) in an exponentially growing culture at any point in time from the following expression:

$$(1) \quad N_t = N_0 2^n$$

where N_t is cell number at time t , N_0 is the initial cell number (the number at time 0), and n is the number of generations during the period of exponential growth.

The equation $N_t = N_0 2^n$ can be solved for n by taking the logarithms of both sides and using algebra to yield

$$(2) \quad n = [(\log N_t - \log N_0) / \log 2]$$

This equation makes it possible to calculate generation times in terms of measurable quantities, N_t and N_0 . Values for N_t and N_0 can

(a)

Exponential Growth Equations

$$g = t/n$$

$$N_t = N_0 2^n$$

$$n = (\log N_t - \log N_0)/0.301$$

$$N_t = N_0 e^{kt}$$

$$k = 0.693/g$$

g : generation time

t : time

N_t : cell number at time t

N_0 : starting cell number

n : number of generations

(b)

Figure 4.12 Calculating microbial growth parameters. Method of estimating the generation times (g) of exponentially growing populations with g of (a) 6 h and (b) 2 h from data plotted on semilogarithmic graphs. The slope of each line is equal to $0.301/g$, and n is the number of generations in the time t . All numbers are expressed in scientific notation; that is, 10,000,000 is 1×10^7 , 60,000,000 is 6×10^7 , and so on. (c) Useful expressions for analyzing microbial growth.

be determined from the viable or microscopic counting methods described earlier; alternatively, OD readings from a spectrophotometer can be used for these calculations (Sections 4.3–4.5 describe methods for quantifying cell numbers). As an example, consider actual growth data from the plot in Figure 4.12b, in which $N_t = 10^8$, $N_0 = 5 \times 10^7$, and $t = 2$ h:

$$n = [(\log N_t - \log N_0)/\log 2]$$

$$n = [\log(10^8) - \log(5 \times 10^7)]/\log 2$$

$$n = (8 - 7.69)/\log 2 = (0.301)/0.301 = 1$$

Thus, in this example $n = 1$ and so we can use the equation $g = t/n$ to determine that $g = 2$ h. If exponential growth continued for another 2 h, the cell number would be 2×10^8 . Two hours later, the cell number would be 4×10^8 , and so on.

The value of g can also be calculated by evaluating the slope of the line on a semilogarithmic plot of exponential growth. On such a plot (Figure 4.12b) the *slope* is defined as $[(\log N_t - \log N_0)/t]$. Combining this with expression (2) and the understanding that $g = t/n$, the slope of the curve reduces to $[\log 2/g]$, or simply, $0.301/g$. In the example shown in Figure 4.12b, the slope is 0.15 h^{-1} , and since $g = 0.301/\text{slope}$, the generation time is $[0.301/0.15 \text{ h}^{-1}] = 2$ h.

Specific Growth Rate

Other expressions are often useful in describing exponential growth, and chief among these is the *specific growth rate* (k). The specific growth rate expresses the rate at which the population is growing at any instant (by contrast, g is the mean time required for the cell population to double); k is expressed in units of reciprocal hours (h^{-1}).

The specific growth rate is a function of the change in cell number (dN/dt) over time and is expressed as $dN/dt = kN$, where the specific growth rate (k) indicates the rate at which the cell number (N) is increasing at any point in time. Integration of this equation using natural logarithms ($\log_e$), gives the expression $N_t = N_0 e^{kt}$. To estimate k , the $\log_{10}$ of both sides of this equation is taken to obtain the expression $\log N_t = kt/2.303 + \log N_0$ ($\log_{10}$ is used such that N can be plotted against t in a semilog plot, Figure 4.12). From this equation, $[(\log N_t - \log N_0)/t]$ reduces to $(k/2.303)$; that is, the slope of the line on a semilogarithmic plot of growth can be calculated as $k/2.303$. Also, since $0.301/g = k/2.303$, k can be expressed directly as $0.693/g$.

Armed with knowledge of n and t , one can calculate g and k for different microorganisms growing under various conditions (Figure 4.12). This is often useful for optimizing culture conditions for

a newly isolated organism and for testing the positive or negative effect of some treatment on a bacterial culture. For example, comparison with an unamended control allows factors that stimulate or inhibit growth to be identified by measuring their effect on the various growth parameters presented here.

Consequences of Exponential Growth

During exponential growth, the increase in cell number is initially rather slow but increases at an ever-faster rate. In the later stages of exponential growth, this results in an explosive increase in cell numbers. For example, in the experiment shown in Figure 4.11, the rate of cell production in the first 30 min of growth is 1 cell per 30 min. However, between 4 and 4.5 h of growth, the rate of cell production is 256 cells per 30 min, and between 5.5 and 6 h of growth it is 2048 cells per 30 min. Because of this, cell numbers in laboratory cultures of bacteria can quickly become very large, and population sizes of $>10^9$ cells/ml are common.

Besides being a theoretical consideration, exponential growth can have implications in everyday life. Consider something we have all experienced, the spoilage of milk. The lactic acid bacteria responsible for the soured flavor of spoiled milk contaminate the milk during its collection and exist in fresh, pasteurized milk in low numbers; these organisms grow slowly at refrigerator temperature (4°C) but much faster at room temperature. If a bottle of fresh milk stands at room temperature overnight, some lactic acid is made, but not enough to affect milk quality. However, if week-old milk, which now contains a week's worth of slow bacterial growth (and thus much higher cell numbers), is left standing under the same conditions, a huge amount of lactic acid is made, and spoilage results.

Check Your Understanding

- What is a *semilogarithmic* plot and what information can we derive from it?
- For an exponentially growing culture that increases from 5×10^6 cells/ml to 5×10^8 cells/ml in 8 h, calculate g , n , and k .
- For testing a bacterium's response to an inhibitory substance, why would g be useful information?

4.8 Continuous Culture

Up to this point our consideration of microbial population growth has been confined to *batch cultures*. The environment in a batch culture is constantly changing because of nutrient consumption and waste production. These limitations can be circumvented in a *continuous culture device*. The most common type of continuous culture device is the **chemostat** (Figure 4.13). Unlike a batch culture, which is a *closed* system, a continuous culture is an *open* system. In a chemostat, a known volume of sterile medium is added at a constant rate while an equal volume of spent culture medium (which also contains cells) is removed at the same rate (Figure 4.13). Once in equilibrium, the culture volume, cell number, and nutrient/waste product status remain constant, and the culture attains *steady state*.

The Chemostat and the Concept of Steady State

A chemostat enables control over both the specific growth rate (k , Figure 4.14) and growth yield (biomass per ml, Figure 4.15) of a microbial culture. In a chemostat, fresh sterile medium is added to a culture vessel and spent media washed out at equal rates, resulting in

a culture that maintains a fixed volume (Figures 4.13 and 4.14). The supply of medium is defined by the dilution rate (D) which is expressed as F/V , where F is the flow rate (volume per unit time), and V is the culture volume. In the chemostat, the specific growth rate is controlled by the *dilution rate* (D), and the growth yield is controlled by the *concentration of a limiting nutrient* in the fresh medium added to the vessel.

In a chemostat at steady state, cells grow at the same rate that they are removed by outflow from the system; that is, $k = D$ (Figure 4.14). At steady state, a large number of cells are all competing for a limiting nutrient. The nutrient added in the fresh medium is consumed rapidly by the cells within the chemostat, thereby limiting their growth rate. As the flow of nutrients increases, the cells can grow faster and they continue to keep pace with the dilution rate until it is so fast that it exceeds the maximal growth rate of the organism. At this point, the cells can no longer keep up and they are washed out of the culture vessel (Figure 4.14).

While the specific growth rate is controlled by D , the growth yield is controlled

Figure 4.14 Steady-state relationships in the chemostat. The dilution rate is determined from the flow rate and the volume of the culture vessel. Note that at a high dilution rate, growth cannot balance dilution, and the population washes out. Note also that although the population density (bacterial biomass) remains constant and the concentration of the growth-limiting nutrient remains near zero during steady state, the specific growth rate can vary over a wide range.

by the concentration of the limiting nutrient in the medium (Figure 4.15). As shown in Figure 4.14, a change in D does not change growth yield in terms of biomass present until washout occurs. However, more nutrients in the medium mean that more cells can be made (Figure 4.15) but has no impact on the growth rate (except at very low nutrient concentrations when cells are starving). Thus, by varying D or the concentration of the growth-limiting nutrient, one can establish cultures that are growing exponentially at a defined growth rate and a defined cell density.

Experimental Uses of the Chemostat

A practical advantage of the chemostat is that a cell population can be maintained in the exponential growth phase for long periods—weeks or even months. Exponential phase cells are usually most

Figure 4.15 The effect of nutrients on growth in a chemostat. Relationship between nutrient concentration, growth rate, and growth yield (bacterial biomass) in a chemostat culture. Only at low nutrient concentrations are both growth rate and growth yield affected.

desirable for physiological experiments. Such cells are available at any time in the chemostat, and the vessel can be sampled repeatedly. Chemostat cultures have been used extensively to study bacterial physiology and have also been used in studies of microbial ecology and evolution. For example, because the chemostat can mimic the low substrate concentrations often found in nature, it is possible to ask which organisms in mixed cultures of known composition compete best at various specific growth rates or when particular nutrients are limiting. Chemostats have also been used for the direct enrichment and isolation of bacteria from nature. From a natural sample, one can select a stable population under the chosen conditions of nutrient concentration and D and then slowly increase D until a single organism remains. In this way, microbiologists studying the growth rates of various soil bacteria isolated a bacterium with a 6-min doubling time—the fastest-growing bacterium known!

- What happens in a chemostat if the dilution rate exceeds the maximal specific growth rate of the organism?
- Do pure cultures have to be used in a chemostat?

4.9 Biofilm Growth

Thus far we have considered microbial growth in liquid suspensions only. Such growth of free-floating or free-swimming cells is called *planktonic growth*. Planktonic growth is a natural state for many microbes, and most laboratory cultures are maintained in this state. However, *sessile growth*, meaning growth while attached to a surface, is quite common in the microbial world. Microbes that are attached to surfaces often develop into *biofilms*. Biofilm growth has tremendous importance in medical and industrial applications, and it allows microbes to exhibit different properties from those of planktonic cells.

Biofilm Formation

A **biofilm** is a population of cells enmeshed in a polysaccharide matrix that is attached to a surface (Figure 4.16). Biofilms form in stages, beginning with the *attachment* of planktonic cells to a surface. Attachment is often mediated by flagella, fimbriae, or pili (Chapter 2). *Colonization* of the surface starts when microbes begin to grow and produce sticky extracellular polysaccharides (EPS). Microbial colonization and growth on the surface causes changes in the biofilm that lead to development. During *development*, cells in the biofilm begin to change their metabolism. These changes can cause biofilms to develop complex systems of mushroomlike columns and channels that trigger metabolic differentiation of microbes at the surface of the biofilm from those at its base. Finally, *dispersal* of cells from a mature biofilm allows microbes to colonize new sites (Figure 4.16). Dispersal is usually prompted by changes in the environment, such as nutrient limitation or other forms of stress.

Biofilms can be studied in a *flow chamber*, in which liquid media flows continuously between two layers of glass. Flow chambers are designed so that biofilm growth can be monitored microscopically

Figure 4.16 *Pseudomonas aeruginosa* biofilm development. Confocal scanning laser micrographs of a developing *Pseudomonas aeruginosa* biofilm in a flow cell continuously irrigated with nutrient-rich medium. *P. aeruginosa* cells first attach to the glass surface (day 0), then rapidly grow and move on the surface to cover the entire surface (day 1); by day 4 mushroom-shaped microcolonies over 0.1 mm high have developed.

over time (Figure 4.16). *Pseudomonas aeruginosa* is a model organism that has been used to study biofilms. *P. aeruginosa* is a relevant model because it forms biofilms in the lungs of humans with the genetic disease *cystic fibrosis*. Biofilm formation allows cells of *P. aeruginosa* to persist and resist removal. Biofilms also tend to make bacteria more resistant to drugs because they provide a penetration barrier and promote metabolic differentiation. Hence, biofilms allow complex microbial interactions not observed in planktonic microbes.

Biofilms and Humans

Biofilms are a common growth form for bacteria in nature because the intensely interwoven nature of the structure prevents harmful

chemicals from reaching cells deep within the biofilm structure. Biofilms also provide a physical barrier that protects cells from grazing by protists and allows them to remain in a safe and favorable habitat. Some biofilms form multilayered sheets with different organisms present in the individual layers, and these biofilms are called *microbial mats*. Mats composed of various phototrophic and chemotrophic bacteria are common in the outflows of hot springs (Figure 4.17a) and marine intertidal regions and can form crusty matlike structures quickly in puddles of water that stay moist for as little as a few days.

Biofilms affect many aspects of our lives, including human health. For example, biofilms have been implicated in difficult-to-treat infections of human joints, implanted medical devices such as artificial heart valves and joints, and indwelling devices, such as catheters (Figure 4.17b). Biofilms are also responsible for the formation of dental caries (cavities) and are a cause of gum disease. In industrial and municipal settings, biofilms can cause fouling, plugging, and corrosion in pipes used to transport liquids. Biofilms can even form in fuel storage tanks, where they contaminate fuel by producing corrosive chemicals such as H_2S . Finally, the formation of biofilms on the hulls of ships is a major problem because they decrease speed and energy efficiency and thereby increase shipping times and shipping costs.

Biofilms are of tremendous significance and so we will revisit different aspects of the biology of biofilms in Chapters 7 and 20.

4.10 Alternatives to Binary Fission

Planktonic cells that grow by binary fission undergo *balanced growth* during exponential phase. All cells in such a culture are nearly identical, genetically and metabolically, and the uniformity of such cultures makes them desirable as experimental systems. We have already learned that cells within biofilms do not exhibit balanced growth because their metabolic characteristics and growth rates vary widely depending on their position within the biofilm. Here we consider microbes that do not display binary fission and whose growth dynamics are not well explained by standard growth equations.

Budding Cell Division

Although binary fission, which produces identical daughter cells, is common among *Bacteria* and *Archaea*, many bacteria grow by other means. Budding bacteria, for example, exhibit unequal cell growth and produce daughter cells that have different characteristics (Figure 4.18). In **budding division** a new cell emerges and buds off from a mother cell, the latter of which retains its original identity (Figure 4.18).

Some budding bacteria form cytoplasmic extensions such as stalks or hyphae, and classic examples are the genera *Caulobacter* (◀ Figure 2.14) and *Hyphomicrobium* (Figure 4.18). *Hyphomicrobium* forms a long stalk from which a new cell emerges and buds. In the case of *Caulobacter*, the mother cell is attached to a surface by its stalk. The daughter cell that buds off is motile; it lacks a stalk and has a flagellum that allows it to disperse by swimming motility. Other budding bacteria such as the aquatic bacterium *Ancalomicrobium* produce multiple appendages that resemble arms extending away from the cell (▶ Figure 15.53b). The appendages increase the surface-to-volume ratio of the cell (◀ Section 1.3), which increases its ability to extract nutrients from oligotrophic (very dilute) habitats. Many budding bacteria also have distinctive life cycles, and we consider these and the group as a whole in Section 15.18.

Hyphal Growth and Multiple Fission

Actinomycetes are gram-positive filamentous bacteria that are common in soils and grow as long thin filaments called *hyphae*; species of the genus *Streptomyces* are typical actinomycetes (Figure 4.19). **Hyphal growth** occurs only at the tip of an elongating filament and

Figure 4.19 Colorized scanning electron micrograph of cells of *Streptomyces*, a filamentous bacterium that produces arthrospores. Various species of *Streptomyces* are major producers of antibiotics.

I. Equal products of cell division:

Binary fission: most bacteria

II. Unequal products of cell division:

1. Simple budding: *Pirellula*, *Blastobacter*

2. Budding from hyphae: *Hyphomicrobium*, *Rhodomicrobium*, *Pedomicrobium*

3. Cell division of stalked organism: *Caulobacter*

4. Polar growth without differentiation of cell size:

Figure 4.18 Cell division in different morphological forms of bacteria. The contrast is shown between cell division in conventional bacteria (cells that divide by binary fission) and in various budding and stalked bacteria.

is unlike binary fission because growth of the cell is not linked directly to cell division. That is, cells elongate and replicate DNA as they grow but do not produce septa. Instead, hyphae form cross-walls away from the point of cell growth. These cross-walls do not define independent cells but instead allow transport to occur between adjacent compartments in the hyphal filament (see also page 144). Hyphae often weave together to form *mycelia*, which form from complex hyphal filaments, and mature mycelia often form *arthrospores*. Arthrospores are survival structures but differ from endospores in their mechanism of development and their lack of resistance to heat and harsh chemicals.

Arthrospores develop by *multiple fission*, in which a single hyphal filament forms many septa simultaneously along its length. This causes many cells to form all at once along the filament, each of which ultimately differentiates into a mature arthrospore. Multiple fission is also seen in certain cyanobacteria (a defining feature of the *Pleurocapsales*; see ▶ Figure 15.2b). Cells of the cyanobacterium *Stanieria*, for example, begin about 1 μm in diameter and grow to as large as 30 μm in diameter before undergoing multiple fission, a process in which the large cell subdivides into tens (or even hundreds) of smaller cells, each of which begins the replication cycle anew. Finally, some bacteria even form intracellular offspring. Bacteria such as the giant-celled *Epulopiscium* (◀ Figure 1.6a) grow by forming multiple daughter cells within the cytoplasm of the mother cell. Once the daughter cells are mature, they burst out of the mother cell and begin a new round of daughter cell production.

Now we turn our attention from microbial growth itself to environmental characteristics that control microbial growth. We will see that the microbial world is ripe with exceptional organisms able to grow under punishing conditions that can only be labeled extreme.

Check Your Understanding

- Why would it be incorrect to apply the growth equations in Figure 4.12 to an organism like *Stanieria*?
- In a solid environment such as soil, what advantage might hyphal growth provide to a bacterium relative to those that grow by binary fission?
- Compare and contrast the life cycle of *Caulobacter* to the development of a biofilm.

III • Environmental Effects on Growth: Temperature

Having the right set of chemical nutrients in a culture medium is only half the secret of growing microbial cells; the other half is to ensure that the environment is suitable for growth. Temperature is a key factor, but what's warm for one organism may be cold for another.

Even when a microbe is provided with an optimal array of its required nutrients, growth is not a sure thing unless the chemical and physical state of its environment is also suitable. Four environmental factors control microbial growth in a major way: *temperature, pH, water availability, and oxygen*. If any one of these factors is beyond the limits that an organism can tolerate, growth will not occur, even in an otherwise ideal culture medium. In Parts III and IV of this chapter we examine these important environmental factors, beginning with temperature, the key factor affecting the growth and survival of microorganisms.

4.11 Temperature Classes of Microorganisms

At either too cold or too hot a temperature, microorganisms will not be able to grow and may even die. The minimum and maximum temperatures supporting growth vary greatly among different organisms and usually reflect the temperature range and average temperature of the environments the organisms inhabit.

Cardinal Temperatures

Temperature affects microorganisms in two opposing ways. As temperatures rise, the rate of enzymatic reactions increases and growth becomes faster. However, above a certain temperature, proteins or other critical cell components may be denatured or otherwise irreversibly damaged. For every microorganism there is a *minimum* temperature below which growth is not possible, an *optimum* temperature at which growth is most rapid, and a *maximum* temperature above which growth is not possible. These three temperatures, called the **cardinal temperatures** (Figure 4.20), are characteristic of any given microorganism and can differ dramatically between different species. For example, some organisms have growth temperature optima near 0°C, whereas the optima for others can be higher than 100°C. The temperature range throughout which microbial growth is possible is even wider than this, from as low as –15°C to at least 122°C. However, no single organism can grow over this

Figure 4.20 The cardinal temperatures: minimum, optimum, and maximum. The actual values may vary greatly for different organisms (see Figure 4.21).

whole temperature range, as the range for any given organism is typically less than 40°C.

The maximum growth temperature of an organism reflects the temperature above which denaturation of one or more essential cell components, such as a key enzyme, occurs. The factors controlling an organism's minimum growth temperature are not as clear. However, the cytoplasmic membrane must remain in a semifluid state for nutrient transport and bioenergetic functions to take place. That is, if an organism's cytoplasmic membrane stiffens to the point that it no longer functions properly in transport or can no longer develop or consume a proton motive force, the organism cannot grow. In contrast to the minimum and maximum, the growth temperature *optimum* reflects a state in which all or most cellular components are functioning at their maximum rate and typically lies closer to the maximum than to the minimum (Figures 4.20 and 4.21).

Temperature Classes of Organisms

Although there is a continuum of organisms, from those with very low temperature optima to those with high temperature optima, it is possible to distinguish four broad classes of microorganisms in relation to their growth temperature optima: *psychrophiles*, with low temperature optima; *mesophiles*, with midrange temperature optima; *thermophiles*, with high temperature optima; and *hyperthermophiles*, with very high temperature optima (Figure 4.21).

Mesophiles are widespread in nature and are the most commonly studied microorganisms. Mesophiles are found in the intestines of endothermic (warm-blooded) animals and in terrestrial and aquatic environments in temperate and tropical latitudes. *Escherichia coli* is a typical mesophile, and its cardinal temperatures have been precisely defined. The optimum temperature for most strains of *E. coli* is 39°C, the maximum is 48°C, and the minimum is 8°C. Thus, the temperature *range* for *E. coli* is about 40 degrees (Figure 4.21).

Figure 4.21 Temperature and growth response in different temperature classes of microorganisms. The temperature optimum of each example organism is shown on the graph.

Psychrophiles and thermophiles are found in unusually cold and unusually hot environments, respectively. Hyperthermophiles are found in extremely hot habitats such as hot springs, where temperatures can be as hot as 100°C, and deep-sea hydrothermal vents, where temperatures can exceed 100°C. We now consider these fascinating microbes and examine some of the physiological problems they face and some of the biochemical solutions they have evolved to thrive under these extreme conditions.

Check Your Understanding

- How does a hyperthermophile differ from a psychrophile?
- What are the cardinal temperatures for *Escherichia coli*? To what temperature class does it belong?
- *E. coli* can grow at a higher temperature in a complex medium than in a defined medium. Why?

4.12 Microbial Life in the Cold

Because humans live and work in places where temperatures are moderate, it is natural to consider very hot and very cold environments as “extreme.” However, many microbial habitats are indeed very hot or very cold, and organisms that inhabit these environments—called *extremophiles* (◀ Section 1.5 and Table 1.2)—actually thrive in these punishing environments. We consider the biology of these fascinating organisms here and in the next section.

Cold Environments

Much of Earth’s surface is cold. The oceans, which make up over half of Earth’s surface, have an average temperature of 5°C, and the depths of the open oceans have constant temperatures of 1–3°C. Vast areas of the Arctic and Antarctic are permanently frozen or are unfrozen for only a few weeks in summer (Figure 4.22). These cold environments support diverse microbial life, as do glaciers (Figure 4.22e), where the networks of liquid water channels that run

through and under the glacier are teeming with microorganisms. Even in solidly frozen materials there remain small pockets of liquid water where solutes have concentrated and microorganisms can metabolize and grow, albeit very slowly.

In considering cold environments as microbial habitats, it is important to distinguish between environments that are *constantly* cold and those that are only *seasonally* cold. The latter, characteristic of temperate climates, may have summer temperatures as high as 40°C. A temperate lake, for example, may have ice cover in the winter, but the water may remain at 0°C for only a relatively brief time. By contrast, Antarctic lakes contain a permanent ice cover several meters thick (Figure 4.22d), and the water column below the ice in these lakes remains at 0°C or colder year-round. Marine sediments and glaciers are also constantly cold, as are subglacial lakes—lakes deep beneath the glacier surface—and all of these are teeming with microbial life. It is thus not surprising that the best examples of microbes well adapted to cold temperatures have emerged from these environments.

Psychrophilic and Psychrotolerant Microorganisms

A **psychrophile** is a microbe with an optimal growth temperature of 15°C or lower, a maximum growth temperature below 20°C, and a minimum growth temperature of 0°C or lower. By contrast, microbes that grow at 0°C but have optima of 20–40°C are called **psychrotolerant**. Psychrophiles are found in environments that are constantly cold and may even be killed by warming to moderate temperatures. For this reason, the laboratory study of psychrophiles requires that great care be taken to ensure that they never warm up during sampling, transport to the laboratory, isolation, or other manipulations.

Psychrophilic algae and bacteria often grow in dense masses within and under sea ice (frozen seawater that forms seasonally) in polar regions (Figure 4.22a–c). They can also be found on the surfaces of permanent snowfields and glaciers where they impart a

Most organisms are either diatoms or green algae (both eukaryotic phototrophs). (c) Transmission electron micrograph of *Polaromonas*, a gas vesiculate bacterium that lives in sea ice and grows optimally at 4°C. Cells are about 0.8 μm in diameter. (d) Lake Bonney, McMurdo Dry Valleys, Antarctica. Although the lake is permanently ice-covered, the water column under the ice contains a diverse array of *Bacteria*, *Archaea*, and microbial eukaryotes. (e) Garwood Glacier, McMurdo Dry Valleys, Antarctica. The edge of the glacier (arrow) is about 20 m high. Glaciers and subglacial lakes are teeming with microbial life.

distinctive coloration to the surface (Figure 4.23). The snow alga *Chlamydomonas nivalis* is an example of this, the carotenoid pigment astaxanthin in its spores (Figure 4.23 inset) being responsible for the brilliant red color of the snow surface. This alga grows within the snow as a green-pigmented vegetative cell and then sporulates. As the snow dissipates by melting, erosion, and ablation (evaporation and sublimation), the spores become concentrated on the surface. Related species of snow algae contain different carotenoid pigments, and thus fields of snow algae can also be green, orange, brown, or purple.

Several psychrophilic *Bacteria* and a few psychrophilic *Archaea* have been isolated, and some of these show very low growth temperature optima. The permafrost bacterium *Planococcus halocryophilus* grows slowly at -15°C , the lowest growth temperature

documented for any bacterium. However, theoretical considerations of bacterial metabolism suggest that the lower temperature limit for bacterial metabolism is likely to be considerably colder than this. For example, microbial respiration (as measured by CO_2 production) has been measured in tundra soils at nearly -40°C . At a temperature of -20°C , pockets of liquid water can exist in “frozen” materials, and studies have shown that enzymes from cold-active bacteria still function under such conditions. Growth at such temperatures, if possible, would be extremely slow. However, if an organism can grow, even if only at a very low rate, it can remain competitive and maintain a population in its habitat.

Psychrotolerant microorganisms are more widely distributed in nature than are psychrophiles and can be isolated from soils and water in temperate climates as well as from meat, dairy products,

Figure 4.23 Snow algae. Snow bank in the Sierra Nevada, California, with red coloration caused by the presence of snow algae. Inset: photomicrograph of red-pigmented spores of the snow alga *Chlamydomonas nivalis*. Spores are about 18 μm in diameter. The spores germinate to yield motile green algal cells.

cider, vegetables, and fruit stored at standard refrigeration temperatures (4°C). Although psychrotolerant microorganisms grow at 0°C, most do not grow well, and one must often wait weeks before visible growth is seen in laboratory cultures. By contrast, the same organism cultured at 30°C may grow at rates similar to that of many mesophiles. Various *Bacteria*, *Archaea*, and microbial eukaryotes are psychrotolerant.

Molecular Adaptations to Life in the Cold

Psychrophiles produce enzymes that function—often optimally—in the cold and that may be denatured or otherwise inactivated at even very moderate temperatures. The molecular basis for this is not entirely understood, but clearly it is linked to protein structure. Several cold-active enzymes whose structure is known show a greater content of α -helix and lesser content of β -sheet secondary structure (► Section 6.7) than do enzymes that show little or no activity in the cold. Because β -sheet secondary structures tend to be more rigid than α -helices, the greater α -helix content of cold-active enzymes allows these proteins greater flexibility for catalyzing their reactions at cold temperatures. Cold-active enzymes also tend to have greater polar and lesser hydrophobic amino acid content (► Figure 6.27 for structures of amino acids) and lower numbers of weak bonds, such as hydrogen and ionic bonds, compared with the corresponding enzyme from mesophiles. Collectively, these molecular features are likely to keep cold-active enzymes flexible and functional under cold conditions.

Another characteristic feature of psychrophiles is that their cytoplasmic membranes remain functional at low temperatures. Cytoplasmic membranes from psychrophiles tend to have a higher content of unsaturated and shorter-chain fatty acids, and this helps the membrane remain in a semifluid state at low temperatures to carry out important transport and bioenergetic functions. Some

psychrophilic bacteria even contain *polyunsaturated* fatty acids; unlike monounsaturated or fully saturated fatty acids that tend to stiffen at low temperatures, polyunsaturated fatty acids remain flexible even at very cold temperatures.

Other molecular adaptations to cold temperatures include “cold shock” proteins and cryoprotectants, and these are not limited to psychrophiles. Cold shock proteins are a type of molecular chaperone (► Section 6.11) and have several functions that include maintaining cold-sensitive proteins in an active form or binding specific mRNAs and facilitating their translation under cold conditions. Cryoprotectants include dedicated antifreeze proteins or specific solutes—such as glycerol or certain sugars—that are produced in large amounts at cold temperatures; these agents help prevent the formation of ice crystals that can puncture the cytoplasmic membrane. Highly psychrophilic bacteria often produce abundant levels of exopolysaccharide cell surface slime, and these slime layers confer cryoprotection as well.

Although “freezing” temperatures may prevent microbial growth, they do not necessarily cause death. Indeed, just the opposite may occur, and this has been exploited for the preservation of bacterial cells in microbial culture collections. Cells suspended in growth medium containing 10% dimethyl sulfoxide (DMSO) or glycerol as a cryoprotectant and frozen at -80°C (ultracold freezer) or -196°C (liquid nitrogen) remain viable in the frozen state for years.

4.13 Microbial Life at High Temperatures

Microbial life flourishes in high-temperature environments, from sun-heated soils and pools of water to boiling hot springs, and the organisms that live in these environments are typically highly adapted to their environmental temperature. We examine these organisms now and pick up on them again in several later chapters.

Thermal Environments

Organisms whose growth temperature optimum exceeds 45°C are called **thermophiles** and those whose optimum exceeds 80°C are called **hyperthermophiles** (Figure 4.21). The surface of soils subject to full sunlight can be heated to above 50°C at midday, and some surface soils may warm to as high as 70°C . Fermenting materials such as compost piles and silage can also reach temperatures of 70°C . Thermophiles abound in such environments. The most extreme high-temperature environments in nature, however, are hot springs, and these are home to a huge diversity of thermophiles and hyperthermophiles.

Many terrestrial hot springs have temperatures at or near boiling, while those at the bottom of the ocean, called *hydrothermal vents*, can have temperatures of 350°C or greater. Hot springs are found throughout the world, but they are especially abundant in the western United States, New Zealand, Iceland, Japan, Italy, Indonesia,

Central America, and central Africa. The largest concentration of hot springs in the world is in Yellowstone National Park, Wyoming (USA). Although some hot springs vary widely in temperature, many have nearly constant high temperatures, varying less than a degree or two over many years. In addition, different springs have different chemical compositions and pH values. In habitats hotter than 65°C, only prokaryotic cells can thrive (Table 4.3), but the diversity of *Bacteria* and *Archaea* in such environments is often extensive.

Hyperthermophiles and Thermophiles

A variety of hyperthermophiles inhabit boiling hot springs (Figure 4.24), including both chemoorganotrophic and chemolithotrophic species. Growth rates of hyperthermophiles can be studied in the field by immersing a microscope slide into a spring and then examining it microscopically over time. The slide is an excellent surface for microbial attachment and subsequent growth, and so small microbial colonies form (Figure 4.24b) and growth rates can be calculated from cell number data. Ecological studies such as this have shown that growth rates in boiling springs are often quite high, with generation times (*g*) as short as 1 h not uncommon.

Cultures of diverse hyperthermophiles have been obtained, and a variety of morphological and physiological types of both *Bacteria* and *Archaea* are known. Some hyperthermophilic *Archaea* have growth-temperature optima above 100°C, while no species of *Bacteria* have yet been discovered that grow above 95°C. Growing laboratory cultures of organisms with optima above the boiling point requires pressurized vessels that permit temperatures in the growth medium to rise above 100°C without boiling. The most heat-tolerant organisms known inhabit hydrothermal vents, with the most thermophilic example thus far being *Methanopyrus*, a

Figure 4.24 Growth of hyperthermophiles in boiling water. (a) Boulder Spring, a small boiling spring in Yellowstone National Park. This spring is superheated, having a temperature 1–2°C above the boiling point. The mineral deposits around the spring consist mainly of silica and sulfur. (b) Photomicrograph of a microcolony of *Archaea* that developed on a microscope slide immersed in such a boiling spring.

methane-producing genus of *Archaea* capable of growth at up to 122°C (► Section 17.12).

In contrast to hyperthermophiles, thermophiles (optima 45–80°C) inhabit moderately hot or intermittently hot environments. As boiling water leaves a hot spring, it gradually cools, setting up a thermal gradient. Along this gradient, microorganisms become established, with different species growing in the different temperature ranges (Figure 4.25a). By studying the species distribution along such natural thermal gradients, it has been possible to determine the upper temperature limits for various classes of microbes (Table 4.3). Thermophilic *Bacteria* and *Archaea* have also been found in artificial thermal environments, such as hot water heaters. Hot water discharges from power plants and other artificial thermal sources also provide sites where thermophiles can flourish.

Protein and Membrane Stability at High Temperatures

How do thermophiles and hyperthermophiles survive high temperatures? First, their enzymes and other proteins are much more heat-stable than are those of mesophiles and actually function *optimally* at high temperatures. The heat stability of an enzyme from a hyperthermophile is often due to subtle changes in amino acid sequence from the corresponding enzyme of a mesophile, and these changes affect protein structure and function to resist heat denaturation. Heat-stable proteins also typically show increased ionic bonding

(a)

(b)

Figure 4.25 Hot spring microbes and their heat-stable enzymes. (a) Characteristic V-shaped pattern (shown by the dashed white lines) formed by cyanobacteria at the upper temperature for phototrophic life, 70–73°C, in the thermal gradient formed from a boiling hot spring in Yellowstone National Park. The pattern develops because the water cools more rapidly at the edges than in the center of the channel. (b) In the spring source, hyperthermophiles thrive, and some have been used as sources of heat-stable enzymes, such as pullulanase from *Pyrococcus* (Archaea). Ca²⁺ stabilizes the enzyme above the boiling point.

between basic and acidic amino acids and have highly hydrophobic interiors, factors that also prevent unfolding. Finally, solutes such as di-inositol phosphate, diglycerol phosphate, and mannosylglycerate are produced at high levels in certain hyperthermophiles, and these are thought to help stabilize their proteins against thermal denaturation.

Enzymes from thermophiles and hyperthermophiles have significant commercial uses. Heat-stable enzymes catalyze biochemical reactions at high temperatures and are in general more stable than enzymes from mesophiles, thus prolonging the shelf life of commercial enzyme preparations (Figure 4.25b). A classic example of this is the DNA polymerase isolated from *Thermus aquaticus*—Taq

polymerase—used to automate the repetitive steps in the polymerase chain reaction (PCR), a technique for amplifying DNA and a major tool of modern biology (► Section 12.1). Several other heat-stable enzymes are commercially available for specific industrial applications (Figure 4.25b).

Besides enzymes and other macromolecules in the cell, the cytoplasmic membranes of thermophiles and hyperthermophiles must be heat-stable. Heat naturally works to peel apart the lipid bilayer that makes up the cytoplasmic membrane (◄ Section 2.1). In thermophiles and most hyperthermophilic *Bacteria*, the cytoplasmic membrane has a higher content of long-chain and saturated fatty acids and a lower content of unsaturated fatty acids than are found in the cytoplasmic membranes of mesophiles. Saturated fatty acids form a stronger hydrophobic environment than do unsaturated fatty acids, and longer-chain fatty acids have a higher melting point than shorter-chain fatty acids; collectively, these properties increase membrane stability.

Hyperthermophiles, most of which are *Archaea*, do not contain fatty acids in their membranes but instead have C₄₀ hydrocarbons composed of repeating units of isoprene bonded by ether linkage to glycerol phosphate (◄ Figure 2.3). In addition, however, the architecture of the cytoplasmic membranes of many hyperthermophiles takes a unique twist: The membrane forms a lipid *monolayer* rather than a lipid *bilayer* (◄ Figure 2.3c). The monolayer structure covalently links both halves of the membrane and prevents it from melting at the high growth temperatures of hyperthermophiles. We consider other aspects of heat stability in hyperthermophiles, including that of DNA stability, in Chapter 17.

Check Your Understanding

IV • Environmental Effects on Growth: pH, Osmolarity, and Oxygen

Although temperature has an overarching effect on microbial growth, pH, salinity, and atmospheric conditions also control growth of laboratory cultures and natural populations. The best conditions for one organism may differ considerably from those for another.

As we have seen, temperature has a major effect on the growth of microorganisms. But many other environmental factors can affect microbial growth as well, including pH, osmolarity, and oxygen.

4.14 Effects of pH on Microbial Growth

Acidity or alkalinity of a solution is expressed by its **pH** on a logarithmic scale in which neutrality is pH 7 (Figure 4.26). pH values less than 7 are *acidic* and those greater than 7 are *alkaline*. In analogy to a temperature range (Figure 4.21), every microorganism has a pH range, typically about 2–3 pH units, within which growth is possible. Also, each organism shows a well-defined pH optimum, where growth occurs best. Most natural environments have a pH between 3 and 9, and organisms with pH growth optima in this range are most common. Terms used to describe organisms that grow best in particular pH ranges are shown in Table 4.4.

Acidophiles

Organisms that grow optimally at a pH value in the range termed *circumneutral* (pH 5.5 to 7.9) are called **neutrophiles**. For example, the bacterium *Escherichia coli* is a neutrophile (Table 4.4). By contrast, organisms that grow best below pH 5.5 are called **acidophiles**. There are different classes of acidophiles, some growing best at moderately acidic pH and others at very low pH. Many fungi and bacteria grow best at pH 5 or even below, while a more restricted number grow best below pH 3. An even more restricted group grow best below pH 2 and those with pH optima below 1 are extremely rare. Most acidophiles cannot grow at pH 7 and many cannot grow at pH values more than two units above their optimum.

A critical factor governing acidophily is the stability of the cytoplasmic membrane. When the pH is raised to neutrality, the cytoplasmic membranes of strongly acidophilic bacteria are destroyed and the cells lyse. This indicates that these organisms are not just acid-tolerant but that high concentrations of protons are actually *required* for

Figure 4.26 The pH scale. Although some microorganisms can live at very low or very high pH, the cell's internal pH remains near neutrality.

TABLE 4.4 Relationships of microorganisms to pH

Physiological class (optima range)	Approximate pH optimum for growth	Example organism ^a
Neutrophile (pH > 5.5 and < 8)	7	<i>Escherichia coli</i>
Acidophile (pH < 5.5)	5	<i>Rhodospila globiformis</i>
	3	<i>Acidithiobacillus ferrooxidans</i>
	1	<i>Picrophilus oshimae</i>

	9	<i>Bacillus firmus</i>
	10	<i>Natronobacterium gregoryi</i>

^a*Picrophilus* and *Natronobacterium* are Archaea; all others are Bacteria.

cytoplasmic membrane stability. For example, the most acidophilic microbe known is *Picrophilus oshimae*, a species of Archaea that grows optimally at pH 0.7 and 60°C. Above pH 4, cells of *P. oshimae* spontaneously lyse. As one would predict, *P. oshimae* inhabits extremely acidic thermal soils associated with volcanic activity.

Alkaliphiles

A few extremophiles have very high pH optima for growth, sometimes as high as pH 10, and some of these can still grow, albeit poorly, at even higher pH. Microorganisms showing pH optima of 8 or higher are called **alkaliphiles**. Alkaliphilic microorganisms are typically found in highly alkaline habitats, such as soda lakes and high-carbonate soils. The best-studied alkaliphilic bacteria are certain *Bacillus* species, such as *Bacillus firmus*. This organism is alkaliphilic but has an unusually broad range for growth, from pH 7.5 to 11. Some extremely alkaliphilic microbes are also halophilic (salt-loving), and most of these are Archaea (► Section 17.1). Some phototrophic purple bacteria (► Sections 15.4 and 15.5) are also strongly alkaliphilic. Certain alkaliphiles have commercial uses because they excrete hydrolytic enzymes such as proteases and lipases that maintain their activities at alkaline pH. These enzymes are added to laundry detergents to remove protein and fat stains, respectively, from clothing.

Managing membrane bioenergetics is an obvious problem for alkaliphiles. *B. firmus* uses sodium (Na⁺) rather than H⁺ to drive transport reactions and rotate its flagellum; that is, it forms a *sodium* motive force instead of a *proton* motive force. Remarkably, however, *B. firmus* uses a proton motive force to drive ATP synthesis even though the external membrane surface is highly alkaline. Exactly how this happens is unclear, although it is thought that hydrogen ions are in some way kept very near the outer surface of the cytoplasmic membrane such that they cannot spontaneously combine with the abundant hydroxyl ions to form water.

Cytoplasmic pH and Buffers

The optimal pH for growth of an organism refers to the *extracellular* environment only; the *intracellular* pH must be maintained at a value consistent with the stability of macromolecules, a range of about 4 pH units from pH 5 to 9. Thus, despite conditions in their

habitats, extreme acidophiles and alkaliphiles maintain cytoplasmic pH values nearer to neutrality.

To prevent major shifts in pH during microbial growth in batch cultures, *buffers* are commonly added to culture media along with the nutrients required for growth. However, any given buffer works over only a relatively narrow pH range. For neutrophilic species, potassium phosphate (KH₂PO₄) or sodium bicarbonate (NaHCO₃) is often employed. Various organic buffers are available for the growth of acidophiles and alkaliphiles and are widely used for assaying enzymes extracted from cells. The buffer keeps the enzyme solution at optimal pH during the assay, thus ensuring that the enzyme remains catalytically active and unaffected by any protons or hydroxyl ions generated in the enzymatic reaction.

Check Your Understanding

- How does the concentration of H⁺ change when a culture medium at pH 5 is adjusted to pH 9?
- What terms are used to describe organisms whose growth pH optimum is very high? Very low?
- In terms of pH, what class of organism is the bacterium *Escherichia coli*?

4.15 Osmolarity and Microbial Growth

Water is the solvent of life, and water availability is an important factor affecting the growth of microorganisms. Water availability depends not only on how moist or dry an environment is but also on the concentration of solutes (salts, sugars, or other substances) dissolved in the water that is present. Solutes bind water, making it less available to organisms. Hence, for organisms to thrive in high-solute environments, physiological adjustments are necessary. Water availability is expressed in terms of **water activity (*a_w*)**, the ratio of the vapor pressure of air in equilibrium with a substance or solution to the vapor pressure of pure water. Values of *a_w* vary between 0 (no free water) and 1 (pure water); some *a_w* values are listed in Table 4.5.

Water diffuses from regions of higher water concentration (lower solute concentration) to regions of lower water concentration (higher solute concentration) in the process of *osmosis*. The cytoplasm of a cell typically has a higher solute concentration than the environment, so the tendency for water is to diffuse into the cell. Under such conditions, the cell is said to be in *positive water balance*, which is the normal state of the cell. However, when a cell is placed in an environment where the solute concentration exceeds that of the cytoplasm, water will flow out of the cell. If a cell has no strategy to counteract this, it will become dehydrated and unable to grow.

Halophiles and Related Organisms

In nature, osmotic effects are of interest mainly in habitats with high concentrations of salts. Seawater contains about 3% sodium chloride (NaCl) plus small amounts of many other minerals and elements. Microorganisms that inhabit marine environments almost always show an NaCl requirement and grow optimally at the *a_w* of seawater, 0.98 (Table 4.6). Such organisms are called **halophiles**. The requirement for NaCl by halophiles is absolute and cannot be replaced by other salts, such as potassium chloride (KCl), calcium chloride (CaCl₂), or magnesium chloride (MgCl₂).

TABLE 4.5 Water activity of several substances		
Water activity (<i>a_w</i>)	Material	Example organisms ^a
1.000	Pure water	<i>Caulobacter</i> , <i>Spirillum</i>
0.995	Human blood	<i>Streptococcus</i> , <i>Escherichia</i>
0.980	Seawater	<i>Pseudomonas</i> , <i>Vibrio</i>
0.950	Bread	Most gram-positive rods
0.900	Maple syrup, ham	Gram-positive cocci such as <i>Staphylococcus</i>
0.850	Salami	<i>Saccharomyces rouxii</i> (yeast)
0.800	Fruit cake, jams	<i>Zygosaccharomyces bailii</i> (yeast), <i>Penicillium</i> (fungus)
0.750	Salt lakes, salted fish	<i>Halobacterium</i> , <i>Halococcus</i>
0.700	Cereals, candy, dried fruit	<i>Xeromyces bisporus</i> and other xerophilic fungi

^aSelected examples of *Bacteria* and *Archaea* or fungi capable of growth in culture media adjusted to the stated water activity.

Although halophiles require at least some NaCl for growth, the NaCl optimum varies with the organism and is habitat dependent (Figure 4.27). For example, marine microorganisms typically grow best with 1–4% NaCl, organisms from hypersaline environments (environments that are more salty than seawater) grow best at 3–12% NaCl, and organisms from extremely hypersaline environments require even higher levels of NaCl. Organisms isolated from brackish waters (a mixture of freshwater and seawater) may or may not be halophilic.

In contrast to halophiles, **halotolerant** organisms can tolerate some level of dissolved solutes but grow best in the absence of the

Figure 4.27 Effect of NaCl concentration on growth of microorganisms of different salt tolerances or requirements. The optimum NaCl concentration for marine microorganisms such as *Aliivibrio fischeri* is about 5%; for extreme halophiles, it is between 15 and 30%, depending on the organism.

Extremely halophilic <i>Archaea</i> (<i>Halobacterium</i>) and some <i>Bacteria</i> (<i>Salinibacter</i>)	KCl	0.75
Halophilic green algae (<i>Dunaliella</i>)	Glycerol	0.75
Haloalkaliphilic <i>Archaea</i> (<i>Natrinema</i>)	KCl	0.68
Xerophilic and osmophilic yeasts (<i>Zygosaccharomyces</i>)	Glycerol	0.62 ^d
Xerophilic filamentous fungi (<i>Xeromyces</i>)	Glycerol	0.605 ^d

^aSee Figure 6.27 for the structures of amino acids.

^bStructures not shown. Like sucrose, trehalose is a C₁₂ disaccharide; glucosylglycerol is a C₉ alcohol; mannitol is a C₆ alcohol.

^cTo achieve an osmotic a_w lower than about 0.77, solutes other than just NaCl are necessary; for example, other salts (MgCl₂, MgSO₄, or CaCl₂) or nonsalts, such as glycerol or sucrose. For most organisms listed (other than for the xerophiles), the lower a_w for growth can be extended downward somewhat by additional solutes.

^dGrowth of *Zygosaccharomyces* tested in high-sucrose medium. Germination of *Xeromyces* spores tested using matric water potential.

added solute (Figure 4.27). Halophiles capable of growth in very salty environments are called **extreme halophiles** (Figure 4.27). These organisms require very high levels of NaCl, typically 15–30%, for optimum growth and are often unable to grow at all at NaCl concentrations below this. Organisms able to live in environments high in sugar are called **osmophiles**, and those able to grow in very dry environments (made dry by lack of water rather than by dissolved solutes) are called **xerophiles**. Examples of these various classes of organisms are given in Table 4.6.

From growth data obtained from extremely halophilic representatives of all three domains of life, there appears to be a common lower water activity limit for living organisms, and this limit is 0.61. This lower limit is likely set by the physiochemical constraints on obtaining water in osmotic environments of a_w less than 0.6 that

cannot be overcome through biochemical adaptations by the cell. *Matric water activity*, a measure of water bound to a surface, is measured in the same way as osmotic water activity but can drop to significantly lower than 0.6 and still contain viable microbial communities. For example, hyper-arid hot desert soils can have matric a_w values as low as 0.1 during daylight hours. But these environments absorb moisture at night and during rain events, and these increase the water activity to above 0.6, making conditions suitable for microbial metabolism and growth.

Compatible Solutes

When an organism is transferred from a medium of high a_w to one of low a_w , it maintains positive water balance by increasing its internal

solute concentration. This is possible either by pumping solutes into the cell from the environment or by synthesizing a cytoplasmic solute (Table 4.6). In either case, the solute must not inhibit biochemical processes in the cell and is thus called a **compatible solute**.

Compatible solutes are highly water-soluble organic molecules and include sugars, alcohols, and amino acid derivatives (Table 4.6). Glycine betaine, an analog of the amino acid glycine, is widely distributed among halophilic bacteria. Other common compatible solutes include sugars such as sucrose and trehalose, dimethylsul-foniopropionate (produced by marine algae), and glycerol, a com-mon solute in xerophilic fungi, organisms that grow at the lowest water activities known (Table 4.6). In contrast to these organic sol-utes, KCl is the compatible solute of extremely halophilic *Archaea*, such as *Halobacterium* (► Section 17.1), and of a few extremely halophilic *Bacteria*.

The concentration of compatible solute in a cell is a function of the levels of solute in its environment, and adjustments are made in response to the challenge from external solutes. However, in any given organism, the maximal level of compatible solute tolerated is a genetically encoded characteristic. As a result, different organisms have evolved to thrive in habitats of different salinities (Tables 4.5 and 4.6). In fact, organisms designated as *nonhalotolerant*, *halotoler-ant*, *halophilic*, or *extremely halophilic* (Figure 4.27) are to some extent a reflection of their genetic capacity to produce or accumulate com-patible solutes.

4.16 Oxygen and Microbial Growth

Oxygen (O₂) is an essential nutrient for many microbes; they are unable to metabolize or grow without it. Other microbes, by con-trast, cannot grow in the presence of O₂ and may even be killed by

it. We therefore see, just as we did for other environmental factors considered in this chapter, *classes* of microorganisms based on their needs or tolerance of O₂.

Oxygen Classes of Microorganisms

Microorganisms can be grouped according to their relationship with O₂ as outlined in Table 4.7. **Aerobes** can grow at full oxygen tensions (air is 21% O₂) and respire O₂ in their metabolism. **Microaerophiles**, by contrast, are aerobes that can use O₂ only when it is present at levels reduced from that in air (microoxic conditions). This is because of the limited capacity of these organ-isms to respire or because they contain some O₂-sensitive molecule such as an O₂-labile enzyme. Many aerobes are **facultative**, mean-ing that under the appropriate nutrient and culture conditions they can grow in the absence of O₂.

Some organisms cannot respire oxygen and are called **anaerobes**. There are two kinds of anaerobes: **aerotolerant anaerobes**, which can tolerate O₂ and grow in its presence even though they cannot respire, and **obligate anaerobes**, which are inhibited or even killed by O₂ (Table 4.7). *Anoxic* (O₂-free) microbial habitats are common in nature and include muds and other sediments, bogs, marshes, water-logged soils, intestinal tracts of animals, sewage sludge, the deep subsurface of Earth, and many other environments. Because there are many habitats for anaerobes, they are very common in nature and highly diverse. As far as is known, obligate anaerobiosis is characteristic of only three groups of microorganisms: a wide vari-ety of *Bacteria* and *Archaea*, a few fungi, and a few protozoa.

Some of the best-known prokaryotic anaerobes are *Clostridium*, a genus of gram-positive endospore-forming *Bacteria*, and the methan-ogens, a group of methane-producing *Archaea*. Among obligate anaerobes, the sensitivity to O₂ varies greatly. Many clostridia, for example, although requiring anoxic conditions for growth, can tol-erate traces of O₂ or even full exposure to air. Others, such as the methanogens, are killed rapidly by O₂ exposure.

Culture Techniques for Aerobes and Anaerobes

For the growth of aerobes, it is necessary to provide extensive aera-tion. This is because the O₂ that is consumed by the organisms

TABLE 4.7 Oxygen relationships of microorganisms				
Group	Relationship to O ₂	Type of metabolism	Example ^a	Habitat ^b
Aerobes				
Obligate	Required	Aerobic respiration	<i>Micrococcus luteus</i> (B)	Skin, dust
Facultative	Not required, but growth better with O ₂	Aerobic respiration, anaerobic respiration, fermentation	<i>Escherichia coli</i> (B)	Mammalian large intestine
Microaerophilic	Required but at levels lower than atmospheric	Aerobic respiration	<i>Spirillum volutans</i> (B)	Lake water
Anaerobes				
Aerotolerant	Not required, and growth no better when O ₂ present	Fermentation	<i>Streptococcus mutans</i> (B)	Oral cavity
Obligate	Harmful or lethal	Fermentation or anaerobic respiration	<i>Methanobacterium formicicum</i> (A)	Sewage sludge, anoxic lake sediments

^aLetters in parentheses indicate phylogenetic status (B, *Bacteria*; A, *Archaea*). Representatives of either domain of prokaryotic cells are known in each category. Most eukaryotes are obligate aerobes, but facultative aerobes (for example, yeast) and obligate anaerobes (for example, certain protozoa and fungi) are known.
^bListed are typical habitats of the example organism; many others could be listed.

during growth is not replaced fast enough by diffusion from the air. Therefore, forced aeration of liquid cultures is needed and can be achieved by either vigorously shaking the flask or tube on a shaker or by bubbling sterilized air into the medium through a fine glass tube or porous glass disk.

For the culture of anaerobes, the problem is not to *provide* O_2 but to *exclude* it. Bottles or tubes filled completely to the top with culture medium and fitted with leakproof closures provide suitably anoxic conditions for organisms that are not overly sensitive to small amounts of O_2 . A chemical called a *reducing agent* may be added to such vessels to remove traces of O_2 by reducing it to water (H_2O). An example is thioglycolate, which is present in thioglycolate broth, a medium commonly used to test an organism's requirements for O_2 (Figure 4.28).

Thioglycolate broth is a complex medium containing a small amount of agar, making the medium viscous but still fluid. After thioglycolate reacts with O_2 throughout the tube, O_2 can penetrate only near the top of the tube where the medium contacts air. Obligate aerobes grow only at the top of such tubes. Facultative organisms grow throughout the tube but grow best near the top. Microaerophiles grow near the top but not right at the top. Anaerobes grow only near the bottom of the tube, where O_2 cannot penetrate, whereas aerotolerant anaerobes grow throughout the tube. The redox indicator dye *resazurin* is present in thioglycolate broth to signal oxidic regions; the dye is pink when oxidized and colorless when reduced and so gives a visual assessment of the degree of penetration of O_2 into the medium (Figure 4.28).

To remove all traces of O_2 for the culture of strict anaerobes, one can incubate tubes or plates in a glass jar flushed with an O_2 -free gas or fitted with an O_2 consumption system (Figure 4.29a). For manipulating cultures in an anoxic atmosphere, special enclosures called *anoxic glove bags* permit work with open cultures in completely anoxic atmospheres (Figure 4.29b).

Figure 4.28 Growth versus O_2 concentration. From left to right, aerobic, anaerobic, facultative, microaerophilic, and aerotolerant anaerobe growth, as revealed by the position of microbial colonies (depicted in this drawing as black dots) within tubes of thioglycolate broth culture medium. A small amount of agar has been added to keep the liquid from becoming disturbed. The redox dye resazurin, which is pink when oxidized and colorless when reduced, has been added as a redox indicator. (a) O_2 penetrates only a short distance into the tube, so obligate aerobes grow only close to the surface. (b) Anaerobes, being sensitive to O_2 , grow only away from the surface. (c) Facultative aerobes are able to grow in either the presence or the absence of O_2 and thus grow throughout the tube. However, growth is better near the surface because these organisms can respire O_2 . (d) Microaerophiles grow away from the most oxidic zone. (e) Aerotolerant anaerobes grow throughout the tube. Growth is not better near the surface because these organisms can only ferment. In nature, many different habitats exist for each of these oxygen classes. In addition, a single habitat, such as a soil particle, may support growth of both aerobes and anaerobes.

Coy Laboratory Products

Figure 4.29 Incubation under anoxic conditions. (a) Anoxic jar. A chemical reaction in the envelope in the jar generates $H_2 + CO_2$. The H_2 reacts with O_2 in the jar on the surface of a palladium catalyst to yield H_2O ; the final atmosphere contains N_2 , H_2 , and CO_2 . (b) Anoxic glove bag for manipulating and incubating cultures under anoxic conditions. The airlock on the right, which can be evacuated and filled with O_2 -free gas, serves as a port for adding and removing materials to and from the glove bag.

Reactants	Products
$O_2 + e^- \rightarrow$	O_2^- (superoxide)
$O_2^- + e^- + 2 H^+ \rightarrow$	H_2O_2 (hydrogen peroxide)
$H_2O_2 + e^- + H^+ \rightarrow$	$H_2O + OH^\bullet$ (hydroxyl radical)
$OH^\bullet + e^- + H^+ \rightarrow$	H_2O (water)

Outcome:
 $O_2 + 4 e^- + 4 H^+ \rightarrow 2 H_2O$

Figure 4.30 Four-electron reduction of O_2 to H_2O by stepwise addition of electrons. All the intermediates formed are reactive and toxic to cells; water is not.

Why Is Oxygen Toxic?

Why are anaerobic microorganisms inhibited in their growth or even killed by oxygen? Molecular oxygen (O_2) per se is not toxic, but O_2 can be converted to toxic oxygen by-products, and it is these that can harm or kill cells not able to deal with them. These include *superoxide anion* (O_2^-), *hydrogen peroxide* (H_2O_2), and *hydroxyl radical* ($OH^\bullet$). All of these are by-products of the reduction of O_2 to H_2O in respiration (Figure 4.30). Flavoproteins, quinones, and iron–sulfur proteins, electron carriers found in virtually all cells (◀ Section 3.8), also catalyze some of these reductions. Thus, regardless of whether it can respire O_2 , an organism exposed to O_2 will experience toxic forms of oxygen, and if not destroyed, these molecules can wreak havoc in cells. For example, superoxide anion and $OH^\bullet$ are strong oxidizing agents that can oxidize macromolecules and any other organic compounds in the cell. Peroxides such as H_2O_2 can also damage cell components but are not as toxic as O_2^- or $OH^\bullet$.

Superoxide Dismutase and Other Enzymes That Destroy Toxic Oxygen

A major requirement for inhabiting an oxic world is to keep toxic oxygen molecules under control. Microbes accomplish this in much the same way as plants and animals do. Superoxide anion and H_2O_2 are the most abundant toxic oxygen species, and all aerobic and aerotolerant cells have enzymes that destroy these compounds (Figure 4.31). The enzymes catalase and peroxidase attack H_2O_2 ,

(a) **Catalase**

(b) **Peroxidase**

(c) **Superoxide dismutase**

(d) **Superoxide dismutase/catalase in combination**

(e) **Superoxide reductase**

Figure 4.31 Enzymes that destroy toxic oxygen species. (a) Catalases and (b) peroxidases are porphyrin-containing proteins, although some flavoproteins may consume toxic oxygen species as well. (c) Superoxide dismutases are metal-containing proteins, the metals being copper and zinc, manganese, or iron. (d) Combined reaction of superoxide dismutase and catalase. (e) Superoxide reductase catalyzes the one-electron reduction of O_2^- to H_2O_2 .

Figure 4.32 Method for testing a microbial culture for the presence of catalase. A heavy loopful of cells from an agar culture was mixed on a slide (right) with a drop of 30% hydrogen peroxide. The immediate appearance of bubbles is indicative of the presence of catalase. The bubbles are O_2 produced by the reaction $H_2O_2 + H_2O_2 \rightarrow 2 H_2O + O_2$.

forming O_2 and H_2O , respectively (Figure 4.31 and Figure 4.32). Superoxide anion is destroyed by the enzyme *superoxide dismutase*, an enzyme that generates H_2O_2 and O_2 from two molecules of O_2^- (Figure 4.31c). Superoxide dismutase and catalase (or peroxidase) thus work in series to convert O_2^- to harmless products (Figure 4.31d).

Aerobes and facultative aerobes typically contain both superoxide dismutase and catalase. Superoxide dismutase is an essential enzyme for aerobes. Some aerotolerant anaerobes lack superoxide dismutase and use protein-free manganese complexes instead to carry out the dismutation of O_2^- to H_2O_2 and O_2 . Such a system is not as efficient as superoxide dismutase, but it is sufficient to protect the cells from O_2^- damage. In some strictly anaerobic *Archaea* and *Bacteria*, superoxide dismutase is absent and instead the enzyme *superoxide reductase* functions to remove O_2^- . Unlike superoxide dismutase, superoxide reductase reduces O_2^- to H_2O_2 without the production of O_2 (Figure 4.31e), thus avoiding exposure of the organism to O_2 .

V • Controlling Microbial Growth

Chemical and physical agents used to control the growth of microorganisms include heat, radiation, and toxic chemicals. Microbial growth control—whether simple disinfection or actual sterilization—is part of our everyday lives and helps curb the transmission of infectious microbes.

Thus far in this chapter we have discussed microbial growth from the perspective of conditions that *promote* their growth. We close by considering the opposite side of the coin, microbial growth *control*.

Many aspects of microbial growth control have significant practical applications. For example, we routinely wash fresh fruits and vegetables to remove attached microorganisms and we inhibit microbial growth on body surfaces by washing. However, neither of these processes kills or removes all microorganisms. Only **sterilization**—the

killing or removal of all microorganisms (including viruses)—ensures that this is the case. In many circumstances, sterility is not required. In others, however, sterilization is absolutely essential.

4.17 General Principles and Microbial Growth Control by Heat

The effects of microorganisms can often be controlled by simply limiting or inhibiting growth. Methods for inhibiting microbial growth include *decontamination*, the treatment of an object or surface to make it safe to handle, and **disinfection**, a process that directly targets pathogens although it may not eliminate all microorganisms. Decontamination can be as simple as wiping off food utensils to remove food fragments (and their attached organisms) before using them, while disinfection requires agents called *disinfectants* that actually kill microorganisms or severely inhibit their growth. Physical methods of microbial growth control are used extensively in industry, medicine, and the home, and we consider three classes of physical controls in this section and the next: heat, radiation, and filtration. Of these three, heat is the most widely used method of physically treating an object or substance to render it sterile.

Heat Sterilization

The effectiveness of heat as a sterilant is quantified by the time required at a given temperature for a 10-fold reduction in the viability of a microbial population. This is called the *decimal reduction time* (D). The relationship between D and temperature is exponential, as the logarithm of D plotted against temperature yields a straight line (Figure 4.33). Moreover, heat killing proceeds more rapidly as the temperature rises. The type of heat is also important: Moist heat has better penetrating power than dry heat and, at a given temperature, inhibits growth or kills cells more quickly than does dry heat.

Another way to characterize the heat sensitivity of an organism is to measure its *thermal death time*, the time it takes to kill all cells at a given temperature. To determine the thermal death time, samples of a cell suspension are heated for different times, mixed with culture medium, and incubated. If all the cells have been killed, no growth is observed in the incubated samples. However, unlike a decimal reduction time measurement that is independent of the original cell number, the thermal death time is greatly affected by population size; a longer time is required to kill all cells in a large population than in a small one.

The presence of endospore-forming bacteria in a heat-treated sample can influence both the decimal reduction and thermal death times. Recall that the mature endospore is very dehydrated and contains calcium dipicolinate and small acid-soluble spore proteins (SASPs) that help confer heat stability on the structure (◀ Section 2.8). The medium in which heating takes place also influences the rate of killing, and this is especially relevant in food canning procedures. Microbial death is more rapid at acidic pH, and acidic foods such as tomatoes, fruits, and pickles are easier to sterilize than neutral-pH foods such as corn and beans. Moreover, high concentrations of sugars, proteins, and fats decrease heat penetration and usually increase the resistance of organisms to heat, whereas high salt concentrations may either increase or decrease heat resistance, depending on the organism.

(a)

(b)

Figure 4.33 The effect of temperature on the heat killing of microorganisms.

(a) The decimal reduction time (D) is the time at which only 10% of the original population of a given organism (in this case, a mesophile) remains viable at a given temperature. For 70°C, $D = 3$ min; for 60°C, $D = 12$ min; for 50°C, $D = 42$ min.

(b) D values for model organisms of different temperature classes: A, mesophile; B, thermophile; C, hyperthermophile.

The Autoclave and Pasteurization

The **autoclave** is a sealed heating device that uses steam under pressure to kill microorganisms (Figure 4.34). Killing of heat-resistant endospores requires heating at temperatures above the boiling point of water at 1 atm. The autoclave places steam under a pressure of 1.1 kg/cm² (15 lb/in²), which yields a temperature of 121°C. At 121°C, the time to achieve sterilization of small amounts of endospore-containing material is about 15 min (Figure 4.34b). If the object to be autoclaved is bulky or large volumes of liquids are to be sterilized, heat transfer to the interior is retarded, and thus the total heating time must be extended. Note that it is not the *pressure* inside the autoclave that kills the microorganisms but the *high temperatures* that are achieved when steam is placed under pressure.

Pasteurization, a process named for the famous early microbiologist Louis Pasteur (◀ Section 1.11), is not the same as

(a)

(c)

(b)

Figure 4.34 The autoclave and moist heat sterilization. (a) The flow of steam through an autoclave. (b) A typical autoclave cycle. The temporal heating profile of a fairly bulky object is shown. The temperature of the object rises and falls more slowly than the temperature of the autoclave. The temperature of the object must reach the target temperature and be held for 10–15 min to ensure sterility, regardless of the temperature and time recorded in the autoclave. (c) A modern research autoclave containing a pressure-lock door and automatic cycle controls.

sterilization. Pasteurization uses heat to significantly reduce rather than totally eliminate the microorganisms found in liquids, such as milk. At the temperatures and times standardized for the pasteurization of food products, all known pathogenic bacteria are killed. In addition, however, by decreasing the overall microbial load, pasteurization increases the shelf life of perishable liquids.

To pasteurize milk, the liquid is passed through a tubular heat exchanger. Careful control of flow rate and the size and temperature of the heat source raises the temperature of the milk to 71°C for 15 sec (or even higher temperatures for shorter time periods; see time–temperature relationships in Figure 4.33), after which it is rapidly cooled. This process is called *flash pasteurization*. *Ultra-high-temperature (UHT) pasteurization* of milk requires heat treatment at 135°C for 1–2 sec and actually sterilizes the milk such that it can be stored at room temperature for long periods without spoilage.

Check Your Understanding

- Why is heat an effective sterilizing agent?
- What steps are necessary to ensure the sterility of material contaminated with bacterial endospores?
- Distinguish between the sterilization of microbiological media and the pasteurization of dairy products.

4.18 Other Physical Control Methods: Radiation and Filtration

In addition to heat, radiation, in particular ultraviolet (UV) light, X-rays, and gamma rays, are also effective microbial killing agents. However, each type of energy has a different mode of action and killing efficacy and thus their applications vary widely.

Ultraviolet and Ionizing Radiation

Ultraviolet radiation between 220 and 300 nm is absorbed by DNA and can cause mutations or have other serious effects on DNA that lead to death of the exposed organism (► Section 9.4). UV radiation is useful for disinfecting surfaces and air and is widely used to decontaminate and disinfect the work surface of laboratory laminar flow hoods equipped with a “germicidal” UV light (Figure 4.35) and air circulating in hospital and food preparation rooms. However, UV radiation has very poor penetrating power, limiting its use to the disinfection of exposed surfaces or air rather than bulk objects such as canned foods or surgical clothing.

Ionizing radiation is electromagnetic radiation of sufficient energy to produce ions and other reactive molecular species from molecules with which the radiation particles collide. The unit of ionizing radiation is the *roentgen*, and the standard for sterilization is the *absorbed radiation dose*, measured in *rads* (100 erg/g) or *grays* (1 Gy = 100 rad). Ionizing radiation is typically generated from X-ray sources or the radioactive nuclides ^{60}Co and ^{137}Cs . These nuclides produce X-rays or gamma rays, both of which have sufficient energy and penetrating power to kill microorganisms in bulk items such as food products and medical supplies.

Table 4.8 shows the dose necessary for a 10-fold reduction (D_{10}) in number of selected microorganisms. The D_{10} value is analogous to the decimal reduction time (D) for heat sterilization, and the killing curve of ionizing radiation yields a similar plot (Figure 4.36; compare with Figure 4.33). As is also true of heat treatments, killing endospores with ionizing radiation is more difficult than killing vegetative cells, and viruses are more difficult to kill than bacteria (Table 4.8). In addition, microorganisms in general are much more resistant to ionizing radiation than are multicellular organisms. For example, the lethal radiation dose for humans can be as low as 10 Gy if delivered over a short time period.

In the United States, radiation is used for the sterilization of such diverse items as surgical supplies, plastic labware, drugs, and even tissue grafts. Certain foods and food products such as fresh produce,

Figure 4.35 A laminar flow hood. An ultraviolet light source prevents contamination of the hood when it is not in use. When the hood is in use, air is drawn into the cabinet through a HEPA filter. The filtered air inside the cabinet is exhausted out of the cabinet, preventing contamination of the inside of the hood. The cabinet provides a contaminant-free workspace for microbial and tissue culture manipulations.

TABLE 4.8 Radiation sensitivity of some representative microorganisms

Type of microorganism	Characteristics	D_{10}^a (Gy)
Bacteria		
<i>Clostridium botulinum</i>	Gram-positive anaerobe; forms endospores	3,300
<i>Deinococcus radiodurans</i>	Gram-negative, radiation-resistant coccus	2,200
<i>Lactobacillus brevis</i>	Gram-positive, rod-shaped	1,200
<i>Bacillus subtilis</i>	Gram-positive aerobe; forms endospores	600
<i>Escherichia coli</i>	Gram-negative, rod-shaped	300
<i>Salmonella enterica</i> (typhimurium)	Gram-negative, rod-shaped	200
Fungi		
<i>Aspergillus niger</i>	Common mold	500
<i>Saccharomyces cerevisiae</i>	Baker's and brewer's yeast	500
Viruses		
Foot-and-mouth	Pathogen of cloven-hoofed animals	13,000
Coxsackie	Human pathogen	4,500

^a D_{10} is the amount of radiation necessary to reduce the initial population or activity level 10-fold (1 logarithm, see Figure 4.36). Gy, grays. 1 Gy is equivalent to 100 rads. The lethal dose for humans is 10 Gy.

poultry, meat products, and spices are also routinely irradiated to ensure that they are sterile or at least free of pathogens and insects.

Filter Sterilization

Heat is an effective way to decontaminate most liquids, but not all substances are stable at high temperature and so heat-sensitive liquids that are not sterilized by radiation are typically sterilized by filtration. For sterilization, a filter with pores of average size $0.2\ \mu\text{m}$ is a minimum requirement; however, even such tiny holes will not

Figure 4.36 Relationship between the survival fraction and the radiation dose of a microorganism. The D_{10} , which is the decimal reduction dose, can be interpolated from the data as shown.

trap most viruses. Commonly used filter pore sizes for the filter sterilization of small volumes, such as laboratory solutions, are 0.45 μm and 0.2 μm .

Several types of filters are in routine use in microbiology, including depth filters, membrane filters, and nucleopore filters. A depth filter is a fibrous sheet made from an array of overlapping paper or glass fibers that traps particles in the network of fibers (Figure 4.37a). Depth filters are important in biosafety applications such as in a biological safety cabinet where air, both into and out of the cabinet, flows through a depth filter called a *HEPA filter*, or

high-efficiency particulate air filter (Figure 4.37a). HEPA filters typically remove 0.3- μm or larger particles from an airstream with an efficiency of greater than 99.9%; however, this does not ensure sterilization.

Membrane filters are the most common filters used for liquid sterilization in the microbiology laboratory (Figure 4.37b and Figure 4.38). Membrane filters are composed of high-tensile-strength polymers manufactured in such a way as to contain a large number of tiny pores. Filtration is accomplished by using a syringe or a pump to force the liquid through the filtration apparatus into a sterile collection vessel (Figure 4.38). Another type of membrane filter is the nucleopore filter. Nucleopore filters are made from a thin polycarbonate film that is treated with radiation and then etched with a chemical, yielding very uniform-sized holes (Figure 4.37c). Nucleopore filters are commonly used to isolate specimens for scanning electron microscopy. Microorganisms removed by filtration from a liquid or a natural sample, such as lake water, can then be observed directly on the filter (Figure 4.37d).

- Distinguish between the major types of sterilization filters used in the microbiology laboratory.

4.19 Chemical Control of Microbial Growth

Chemicals are routinely used to control microbial growth, and an **antimicrobial agent** is a natural or synthetic chemical that kills or inhibits the growth of microorganisms. Agents that actually kill are called *-cidal* agents, with a prefix indicating the type of microorganism killed. Thus, **bactericidal**, **fungicidal**, and **viricidal** agents kill bacteria, fungi, and viruses, respectively. Agents that do not kill but only inhibit growth are called *-static* agents, and include **bacteriostatic**, **fungistatic**, and **viristatic** compounds. We focus here on chemicals commonly used as disinfectants and reserve discussion of the activities of a very important class of chemicals—the antibiotics—for later (► Sections 8.11 and 28.5).

Figure 4.39 Different types of antimicrobial agents. (a) Bacteriostatic agents inhibit but do not kill. (b) Bactericidal agents kill. (c) Bacteriolytic agents lyse cells. In each graph, the arrow indicates the time at which a growth-inhibitory concentration of an antimicrobial agent was added to an exponentially growing culture. The turbidity and viable counts shown are characteristic of each type of agent.

Effect of Antimicrobial Agents on Growth

Mastering
Microbiology
Art Activity:
Figure 4.39
Different types
of antimicrobial
agents

Antibacterial agents are classified as -static, -cidal, or -lytic (cell lysing) by observing their effects on cultures using viable and turbidimetric growth assays (Figure 4.39). Bacteriostatic agents are typically inhibitors of some important biochemical process and bind relatively weakly; if the agent is removed, the cells can resume growing. Some antibiotics, such as the sulfonamides, work in this way. The clinical value of bacteriostatic antibiotics is their ability to keep a pathogenic bacterium from multiplying until the immune system can rid the body of the pathogen. By contrast, bactericidal agents, for example formaldehyde, bind tightly to their cellular targets and by definition kill the cell. However, the dead cells are not lysed, and total cell numbers, reflected in the turbidity of the culture, remain constant (Figure 4.39b). Bacteriolytic agents kill cells by lysing them, and this affects both viable and total cell numbers (Figure 4.39c). Examples of bacteriolytic agents would be a detergent that ruptures the cytoplasmic membrane or the antibiotic penicillin, which inhibits bacterial cell wall synthesis, resulting in cell lysis.

Figure 4.40 Antimicrobial agent susceptibility assay using dilution methods. The assay defines the minimum inhibitory concentration (MIC). A series of increasing concentrations (from left to right) of antimicrobial agent is prepared in the culture medium. Each tube is inoculated with a specific concentration of a test organism, followed by a defined incubation period. Growth, measured as turbidity, occurs in those tubes with antimicrobial agent concentrations below the MIC.

Assaying Antimicrobial Activity

Antimicrobial activity can be measured by determining the smallest amount of the agent needed to inhibit the growth of a test organism, a value called the **minimum inhibitory concentration (MIC)**. One way to determine the MIC of a given agent is to inoculate a series of tubes of liquid growth medium (Figure 4.40) containing a test organism and dilutions of the agent. Following incubation, the tubes are scored for growth (turbidimetrically), and the MIC is revealed as the lowest concentration of antimicrobial agent that completely inhibits growth.

Antimicrobial activity can also be assessed using solid media (Figure 4.41). Known amounts of an antimicrobial agent are added

Figure 4.41 Antimicrobial agent susceptibility assay using diffusion methods. The antimicrobial agent diffuses from paper disks into the surrounding agar, inhibiting growth of susceptible microorganisms.

to filter-paper disks and the disks are arranged on the surface of a uniformly inoculated agar plate. During incubation, the agent diffuses from the disk into the agar, establishing a gradient; the farther a chemical diffuses away from a disk, the lower its concentration. Following an incubation period, a *zone of growth inhibition* forms around disks that released effective chemicals. The zone is a function of several factors, including the amount of antimicrobial agent added to the disk, its solubility and diffusion coefficient, and, most importantly, its overall effectiveness. The disk diffusion assay is routinely used to test clinically isolated pathogenic bacteria for their antibiotic susceptibility (► Section 28.5).

Chemical Antimicrobial Agents

Several antimicrobial agents are used to prevent the growth of human pathogens on inanimate surfaces and on external body

surfaces. These include sterilants, disinfectants, sanitizers, and antiseptics (Table 4.9).

Sterilants destroy all microorganisms, including endospores. Chemical sterilants are used for decontamination or sterilization in situations where it is impractical or impossible to use heat or radiation. Hospitals, clinics, and laboratories, for example, must routinely decontaminate and sterilize heat-sensitive materials such as thermometers, lensed instruments, polyethylene tubing, catheters, and reusable medical and dental equipment. This process of *cold sterilization*, as it is called, employs gases such as ethylene oxide or aldehydes such as formaldehyde or glutaraldehyde to sterilize the devices.

Disinfectants are chemicals that kill microorganisms but not necessarily endospores and are primarily used on surfaces. For example, phenol and cationic detergents are used to disinfect floors,

TABLE 4.9 Antiseptics, sterilants, disinfectants, and sanitizers ^a		
Agent	Mode of action	Use
Antiseptics (germicides)		
Alcohol (60–85% ethanol or isopropanol in water)	Lipid solvent and protein denaturant	Topical antiseptic
Phenol-containing compounds (hexachlorophene, triclosan, chloroxylenol, chlorhexidine)	Disrupts cytoplasmic membrane	Soaps, lotions, cosmetics, deodorants, topical disinfectants; paper, leather, and textile industries
Cationic detergents, especially quaternary ammonium compounds (benzalkonium chloride)	Disrupts cytoplasmic membrane	Soaps, lotions, topical disinfectants; metal and petroleum industries
Hydrogen peroxide (3% solution)	Oxidizing agent	Topical antiseptic
Iodophors (Betadine [®])	Iodinate proteins, rendering them nonfunctional; oxidizing agent	Topical antiseptic
Octenidine	Cationic surfactant, disrupts cytoplasmic membrane	Topical antiseptic
Sterilants, disinfectants, and sanitizers		
Alcohol (60–85% ethanol or isopropanol in water)	Lipid solvent and protein denaturant	General-purpose disinfectant for virtually any surface
Cationic detergents (quaternary ammonium compounds, Lysol [®] and many related disinfectants)	Interacts with phospholipids	Disinfectant/sanitizer for medical instruments, food and dairy equipment
Chlorine gas	Oxidizing agent	Disinfectant for drinking water and electrical/nuclear cooling towers
Chlorine compounds (chloramines, sodium hypochlorite, sodium chlorite, chlorine dioxide)	Oxidizing agent	Disinfectant/sanitizer for medical instruments, food/dairy equipment, and in water purification
Copper sulfate	Protein precipitant	Algicide in swimming pools
Ethylene oxide (gas)	Alkylating agent	Sterilant for temperature-sensitive materials such as plastics
Formaldehyde	Alkylating agent	Diluted (3% solution) as surface disinfectant/sterilant; concentrated (37% solution) as sterilant
Glutaraldehyde	Alkylating agent	Disinfectant or sterilant as 2% solution
Hydrogen peroxide	Oxidizing agent	Vapor used as sterilant
Iodophors (Wescodyne [®])	Iodinate proteins; oxidizing agent	General disinfectant
OPA (ortho-phthalaldehyde)	Alkylating agent	Powerful disinfectant used for sterilizing medical instruments
Ozone	Strong oxidizing agent	Disinfectant for drinking water
Peroxyacetic acid	Strong oxidizing agent	Disinfectant/sterilant
Phenolic compounds	Protein denaturant	General-purpose disinfectant
Pine oils (Pine-Sol [®]) (contains phenolics and detergents)	Protein denaturant	General-purpose disinfectant for household surfaces

^aAlcohols, hydrogen peroxide, and iodophors can be antiseptics, disinfectants, sanitizers, or sterilants depending on concentration, length of exposure, and form of delivery.

tables, bench tops, walls, and so on (Table 4.9) and are important agents of infection control in hospitals and other medical settings. **Sanitizers**, by contrast, are less harsh than disinfectants and reduce microbial numbers but do not sterilize. Sanitizers are widely used in the food industry to treat surfaces such as mixing and cooking equipment, dishes, and utensils, and are also used for dry hand washing when water is unavailable. **Antiseptics**, often called **germicides**, are chemicals that kill or inhibit the growth of microorganisms but are sufficiently nontoxic to animals to be applied to living tissues. Most germicides are used for hand washing or for treating surface wounds (Table 4.9). Certain antiseptics are also effective disinfectants. Ethanol, for example, can be both an antiseptic and a disinfectant, depending on the concentration and exposure time employed.

Several factors affect the efficacy of any chemical antimicrobial agent. For example, many antimicrobial agents are bound and inactivated by organic matter; thus, disinfecting a kitchen countertop littered with spilled foods is more difficult than disinfecting a clean

countertop. Furthermore, bacteria can form biofilms (Section 4.9), covering surfaces of tissue or soiled medical devices with microbial cells embedded in polysaccharides. Biofilms may slow or even completely prevent penetration of antimicrobial agents, reducing or negating their effectiveness. Thus, the ultimate efficacy of any antimicrobial agent must be determined empirically and under the actual conditions of use. Only by actually testing the chemical and assaying for microbial growth both before and after treatment can one be confident that the agent is working as it should.

Check Your Understanding

- Distinguish between the antimicrobial effects of -static, -cidal, and -lytic agents.
- Describe how the minimum inhibitory concentration of an antibacterial agent is determined.
- Distinguish between a sterilant, a disinfectant, and an antiseptic. What is cold sterilization?

CHAPTER REVIEW

I • Culturing Microbes and Measuring Their Growth

- 4.1** Cells are primarily composed of the elements H, O, C, N, P, and S. Nutrients required by a cell in large amounts are called macronutrients while those required in very small amounts, such as trace elements or growth factors, are micronutrients. Proteins are the most abundant class of macromolecules in the cell.

Q What is the major difference between macronutrients and micronutrients? List a few macronutrients and micronutrients.

- 4.2** Culture media supply the nutritional needs of microorganisms and are either defined or complex. Other media, such as selective and differential media, are used for specific purposes. Many microorganisms can be grown in liquid or solid culture media, and pure cultures can be maintained if aseptic technique is practiced.

Q Why would the following medium not be considered a chemically defined medium: glucose, 5 grams (g); NH_4Cl , 1 g; KH_2PO_4 , 1 g; MgSO_4 , 0.3 g; yeast extract, 5 g; distilled water, 1 liter? What is aseptic technique and why is it necessary?

- 4.3** Total cell counts can be done under the microscope using counting chambers and are useful for assessing total cell numbers in a microbial habitat or laboratory culture. Certain stains can be used to target specific cell populations in a sample.

Q When assessing a culture's performance, in which growth phase would total cell counting be suitable, and in which growth phase would knowing the viability of the culture or sample become necessary?

- 4.4** Viable cell counts measure only the living population present in the sample with the assumption that each colony originates from the growth and division of a single cell. Depending on the growth medium and conditions employed, and the nature of the sample, viable counts can be fairly accurate assessments or highly unreliable.

Q How does a viable count differ from a total count?

- 4.5** Turbidity measurements are a rapid and useful method of measuring microbial growth and are based on the fact that cells in suspension scatter light. In order to relate a turbidity value to a cell number, a standard curve plotting these two parameters against one another must first be established.

Q How can turbidity be used as a measure of cell numbers?

II • Dynamics of Microbial Growth

- 4.6** Microbial growth is defined as an increase in cell numbers and is the final result of the doubling of all cell components prior to actual division that yields two daughter cells. Microorganisms show a characteristic growth pattern when inoculated into a fresh culture medium. There is usually a lag phase and then growth commences in an exponential fashion. As essential nutrients are depleted and/or toxic products accumulate, growth ceases and the population enters the stationary phase. Further incubation can lead to cell death.

Q How does the growth pattern of a population of bacteria inoculated into a fresh medium from an old culture differ from the growth pattern of a population inoculated into a fresh medium from a culture in the mid-exponential phase of growth?

- 4.7** Microbial cells undergo exponential growth, and a semi-logarithmic plot of cell numbers with time can reveal the doubling time of the population. Various growth expressions can be calculated from cell number data obtained from an exponentially growing culture. Key expressions here are n , the number of generations; t , time; g , generation time; and k , the instantaneous growth rate constant.

Q How is the generation time (g) of an exponentially growing culture determined?

- 4.8** The chemostat is an open system used to maintain cell populations in exponential growth for extended periods. In a chemostat, the rate at which a culture is diluted with fresh growth medium controls the growth rate of the population, while the cell density (cells/ml) is controlled by the concentration of a growth-limiting nutrient present in the fresh medium.

Q How does a chemostat regulate growth rate and cell density independently?

- 4.9** Biofilms are an alternative growth mode to a suspended (planktonic) lifestyle and consist of a microbial community enmeshed in a sticky polysaccharide matrix attached to a surface. Biofilms promote intercellular communication and offer protection from predation, harmful substances, and being washed away.

Q What happens during each of the steps that occur in the formation of a microbial biofilm?

- 4.10** Most microorganisms grow by binary fission but some grow by budding. Budding bacteria show unequal cell growth and produce daughter cells that have different characteristics. Some bacteria such as the actinomycetes form long filaments called hyphae that grow from their tips.

Q What are the advantages of biofilms as a growth mode over a planktonic lifestyle?

III • Environmental Effects on Growth: Temperature

- 4.11** Temperature is a major environmental factor controlling microbial growth. An organism's cardinal temperatures are the minimum, optimum, and maximum temperatures at which it grows. Microorganisms can be grouped by their cardinal temperature from cold-loving to heat-loving as psychrophiles, mesophiles, thermophiles, and hyperthermophiles.

Q Examine the graph in Figure 4.21. Why is the optimum temperature for an organism usually closer to its maximum than its minimum?

- 4.12** Organisms with temperature optima below 15°C are called psychrophiles, and the most extreme representatives inhabit constantly cold environments. Psychrophiles synthesize macromolecules that remain flexible and functional at cold temperatures but that can be unusually sensitive to warm temperatures.

Q How do the proteins and lipids of psychrophiles differ from those of mesophiles?

- 4.13** Organisms with growth temperature optima between 45 and 80°C are called thermophiles while those with optima greater than 80°C are hyperthermophiles. These organisms inhabit hot environments that can have temperatures even above 100°C. Thermophiles and hyperthermophiles produce heat-stable macromolecules.

Q What are some important biotechnological uses from hyperthermophiles?

IV • Environmental Effects on Growth: pH, Osmolarity, and Oxygen

- 4.14** The acidity or alkalinity of an environment can greatly affect microbial growth. Some organisms grow best at low or high pH (acidophiles and alkaliphiles, respectively), but most organisms grow best between pH 5.5 and 8. The internal pH of a cell must stay relatively close to neutral to prevent the spontaneous destruction of macromolecules at pH extremes.

Q Concerning the pH of the environment and of the cell cytoplasm, in what ways are acidophiles and alkaliphiles different? In what ways are they similar?

- 4.15** The water activity of an aqueous environment is a function of its solute concentration. To survive in high-solute environments, organisms produce or accumulate compatible solutes to maintain positive water balance. Some microorganisms grow best at reduced water potential and some even require high levels of salts for growth.

Q How does a halophile maintain positive water balance while growing in a solution high in NaCl?

- 4.16** Aerobes require O₂ while anaerobes do not and may even be killed by O₂. Facultative organisms can live with or without O₂. Special techniques are needed to grow aerobic and anaerobic microorganisms. Several toxic forms of oxygen can form in the cell, but enzymes are present that neutralize most of them. Superoxide is a major toxic form of oxygen.

Q Contrast an aerotolerant and an obligate anaerobe in terms of sensitivity to O₂ and ability to grow in the presence of O₂. Compare and contrast the enzymes catalase, superoxide dismutase, and superoxide reductase in regard to their substrates and products.

V • Controlling Microbial Growth

- 4.17** Sterilization is the killing of all microbes including viruses, and heat is the most widely used method of sterilization. An autoclave employs moist heat under pressure to achieve temperatures above the boiling point of water. Pasteurization does not sterilize liquids, but it reduces the microbial load and kills pathogens.

Q Contrast the terms thermal death time and decimal reduction time. How would the presence of bacterial endospores affect either value? What time and temperature is necessary to ensure sterility in the autoclave?

- 4.18** Radiation can effectively inhibit or kill microorganisms. Ultraviolet radiation is used for decontaminating surfaces and air, whereas ionizing radiation is used for sterilization where penetration is required. Filters remove microorganisms from air or liquids. Membrane and nucleopore filters are used for sterilization of heat-sensitive liquids and to examine the contents of filtration by microscopy.

Q Describe the effects of a lethal dose of ionizing radiation at the molecular level. What type of filter would be used to filter sterilize a heat-sensitive liquid?

- 4.19** Chemicals that kill organisms are called -cidal agents while those that arrest growth but do not kill are called -static

agents. Antimicrobial agents are tested for efficacy by determining their ability to inhibit growth. Sterilants, disinfectants, and sanitizers are used to decontaminate nonliving material, while antiseptics (germicides) are used to reduce the microbial load on living tissues.

Q Describe the procedure for obtaining the minimum inhibitory concentration (MIC) for a chemical that is bactericidal for *Escherichia coli*. Contrast the action of disinfectants and antiseptics.

APPLICATION QUESTIONS

1. A medium was inoculated with 5×10^6 cells/ml of *Escherichia coli* cells. Following a 1-h lag, the population grew exponentially for 5 h, after which the population was 5.4×10^9 cells/ml. Calculate g and k for this growth experiment.
2. *Escherichia coli* but not *Pyrolobus fumarii* will grow at 40°C, while *P. fumarii* but not *E. coli* will grow at 110°C. What is happening (or not happening) to prevent growth of each organism at the nonpermissive temperature?
3. In which direction (into or out of the cell) will water flow in cells of *Escherichia coli* (an organism found in your large intestine) suddenly suspended in a solution of 20% NaCl? What if the cells were suspended in distilled water? If growth nutrients were added to each cell suspension, which (if either) would support growth, and why?

CHAPTER GLOSSARY

Acidophile an organism that grows best at low pH, typically below pH 5.5

Aerobe an organism that can use O₂ in respiration; some require O₂

Aerotolerant anaerobe a microorganism unable to respire O₂ but whose growth is unaffected by it

Alkaliphile an organism that has a growth pH optimum of 8 or higher

Anaerobe an organism that cannot use O₂ in respiration and whose growth is typically inhibited by O₂

Antimicrobial agent a chemical compound that kills or inhibits the growth of microorganisms

Antiseptic (germicide) a chemical agent that kills or inhibits growth of microorganisms and is sufficiently nontoxic to be applied to living tissues

Aseptic technique a series of steps taken to prevent contamination of laboratory cultures and media

Autoclave a sealed heating device that destroys microorganisms with temperature and steam under pressure

Bactericidal agent an agent that kills bacteria

Bacteriostatic agent an agent that inhibits bacterial growth

Batch culture a closed-system microbial culture of fixed volume

Binary fission cell division following enlargement of a cell to twice its minimum size

Biofilm colonies of microbial cells encased in a porous organic matrix and attached to a surface

Budding division a cell division process whereby new cell material is produced from a single point instead of along the entire cell

Cardinal temperatures the minimum, maximum, and optimum growth temperatures for a given organism

Chemostat a device that allows for the continuous culture of microorganisms with independent control of both growth rate and cell number

Colony morphology the visible appearance of a colony grown on a solid medium

Compatible solute a molecule that is accumulated in the cytoplasm of a cell for adjustment of water activity but that does not inhibit biochemical processes

Complex medium a culture medium of highly nutritious substances for which the exact composition is unknown

Culture medium a nutrient solution required for growing a laboratory culture of a specific microorganism

Decline phase the component of a microbial growth curve during which the rate of cell death exceeds the rate of cell growth

Defined medium a culture medium for which the exact composition is known

Disinfectant an antimicrobial agent used only on inanimate objects

Disinfection rendering a surface or object free of all pathogenic microorganisms

Exponential phase (exponential growth) a condition during which the cell numbers in a microbial population double at regular intervals

Extreme halophile a microorganism that requires very large amounts of NaCl, usually greater than 10% and in some cases near saturation, for growth

Facultative with respect to O₂, an organism that can grow in either its presence or absence

Generation time the time required for a population of microbial cells to double

Germicide (antiseptic) a chemical agent that kills or inhibits growth of microorganisms and is sufficiently nontoxic to be applied to living tissues

Growth curve the dynamics of microbial growth observed in batch culture, consisting of four phases: lag, exponential, stationary, and decline

Halophile a microorganism that requires NaCl for growth

Halotolerant a microorganism that does not require NaCl for growth but can grow

in the presence of NaCl, in some cases, substantial levels of NaCl

Hyperthermophile a species of *Bacteria* or *Archaea* whose growth temperature optimum is 80°C or greater

Hyphal growth a form of growth in which cells elongate only at the tip of a growing filament

Lag phase the component of a microbial growth curve prior to the onset of growth

Mesophile an organism that grows best at temperatures between 20 and 40°C

Microaerophile an aerobic organism that can grow only when O₂ tensions are reduced from that present in air

Minimum inhibitory concentration (MIC)
The smallest amount of an antimicrobial substance that prevents growth of the target microorganism

Neutrophile an organism that grows best at neutral pH, between pH 5.5 and 8

Obligate anaerobe an organism that cannot grow in the presence of O₂

Osmophile an organism that grows best in the presence of high levels of solute, typically a sugar

Pasteurization the heat treatment of milk or another liquid to reduce its total number of microorganisms

pH the negative logarithm of the hydrogen ion (H⁺) concentration of a solution

Plate count a method for counting viable cells; the number of colonies on a plate is used as a measure of cell numbers

Psychrophile an organism with a growth temperature optimum of 15°C or lower and a maximum growth temperature below 20°C

Psychrotolerant capable of growing at low temperatures but having an optimum above 20°C

Sanitizer an agent that reduces microorganisms to a safe level, but may not eliminate them

Stationary phase the component of a microbial growth curve during which the rate of growth and death are approximately equal

Sterilant a chemical agent that destroys all forms of microbial life

Sterilization the killing or removal of all living organisms and viruses

Thermophile an organism whose growth temperature optimum lies between 45 and 80°C

Viable capable of reproducing

Viable count a measurement of the number of live cells in a population

Water activity the ratio of the vapor pressure of air in equilibrium with a solution to the vapor pressure of pure water

Xerophile an organism that is able to live, or that lives best, in very dry environments

5 Viruses and Their Multiplication

- I The Nature of Viruses 185
- II Overview of the Viral Replication Cycle 191

MICROBIOLOGYNOW

When Antibiotics Fail, Bacteriophage Therapy to the Rescue

Acquiring an antibiotic-resistant infection or “superbug” is one of medicine’s biggest nightmares. What can medical practitioners do to treat the patient? Besides drugs, viruses known as bacteriophages have been recruited to specifically target and kill bacteria.

Despite microbiologists’ tinkering with using bacteriophages as antimicrobials for decades, their actual application in medicine has been minimal. However, the emergence of antibiotic resistance has led to renewed focus on using these tiny microbes as therapeutic agents. The photo above shows Ella Balasa (right side of photo), a microbiologist who has cystic fibrosis. Cystic fibrosis is a genetic disease that results in a buildup of thick mucus in the lungs. This mucus allows bacteria to flourish in the lungs, which results in infections and subsequent lung damage that can be fatal. Ella had been treated numerous times with strong antibiotics specific for a respiratory infection caused by the bacterial pathogen *Pseudomonas aeruginosa*, but the microbial cells had become unresponsive to the drugs. At the time of this photo,

the recurrent infection had decreased her lung function to the point where she required constant supplemental oxygen.

As an alternative treatment route, Dr. Benjamin Chan (on the left) took mucus from Ella’s lungs infected with *P. aeruginosa* and isolated a bacteriophage that specifically killed the pathogen (see zones of clearing on Petri plate). This bacteriophage was propagated and then poured into a device so that Ella could inhale the therapy. The result of her treatment? Amazingly, the bacteriophage therapy along with a mixture of antibiotics resulted in the infection clearing a few weeks later!

While bacteriophage therapy is limited by bacterial host specificity and the ability of the pathogenic bacteria to become resistant to viral infection, this trial and other recent success stories illustrate the future promise of phage therapy when all other options fail.

Source: Kortright, K.E., B.K. Chan, J.L. Koff, and P.E. Turner. 2019. Phage therapy: A renewed approach to combat antibiotic-resistant bacteria. *Cell Host Microbe* 25(2): 219.

Thus far in Unit 1 we have focused on the fundamentals of the three phylogenetic groups of cells—*Bacteria*, *Archaea*, and microbial *Eukarya*—by highlighting their structure, growth, and overall impact on the biosphere. Here we shift gears and discuss the most abundant microbes on Earth—viruses. With the population of viruses estimated to outnumber bacterial and archaeal cells by a factor of 10, viruses have a huge impact on the biosphere and have a unique biology reminiscent of, yet distinct from, that of the cellular world.

The study of viruses is the science of *virology*, and this chapter covers the basic principles needed to understand their biology. In Chapter 11 we consider the genomic, replication, and diversity aspects of viruses in detail, and in Unit 7 we consider pathogenic viruses and the extensive role they play in governing human health and disease.

I • The Nature of Viruses

Viruses are noncellular microbes that show many of the properties of cells except that viruses absolutely require a growing host cell in order to multiply. Viral diversity in nature is enormous, virus densities can be quantified, and cells in all domains of life are susceptible to viral infection.

5.1 What Is a Virus?

A **virus** is a genetic element that can multiply only inside a living cell, called the **host cell**. Not considered living entities, viruses are

not found on the tree of life (◀ Figure 1.41b). Viruses rely on the host cell for energy, metabolic intermediates, and protein synthesis, and so they are *obligate intracellular parasites*. However, viruses possess their own nucleic acid genomes and in this sense are independent of the host's genome. Viruses infect cells in all three domains of life and are responsible for many infectious diseases of humans, plants, and other organisms.

Although viruses are not cells, their genomes encode those functions needed to multiply and they have a structurally intricate extracellular form, called the **virion** (Figure 5.1); the virion allows the virus to travel from one host cell to another. Viruses cannot reproduce unless the virion itself, or in some cases its genome only, has gained entry into a suitable growing host cell, a process called *infection*.

Viral Components and Activities

Virions are composed of a protein shell, called the **capsid**, and the virus genome that the capsid contains. Most bacterial and plant viruses are *naked*, with no further layers, whereas many other types of viruses, especially animal viruses, have an outer layer. If the layer is composed of a phospholipid bilayer taken from the host cell membrane, it is called the *envelope* (Figure 5.2). In enveloped viruses, the inner structure of nucleic acid plus capsid protein is called the **nucleocapsid**. The virion protects the viral genome when the virus is outside the host cell, and proteins on the virion surface are important in attaching it to its host cell. The virion may also contain one

or more virus-specific enzymes that play a role during infection and replication, as discussed later.

Once inside the host cell, a viral genome can orchestrate one of two quite different events. The virus may replicate and destroy the host in a *virulent infection* via a **lytic pathway**. In a lytic infection, the virus redirects the host cell's metabolism from growth to support virus multiplication and the assembly of new virions. Eventually, new virions are released, and the process can repeat itself within new host cells. Alternatively, some viruses can cause a *lysogenic infection*; in this case, the host cell is not destroyed and the viral genome becomes part of the host genome. These types of infection are discussed in detail later in the chapter (Section 5.6).

Viral Diversity and Hosts

While all cells contain double-stranded DNA genomes, viruses often break this rule by having genomes that consist of either DNA or RNA and are further subdivided based on whether the genome is *single-stranded* or *double-stranded*. As one might expect, this interesting feature of viral genomes requires special processes for genetic information flow (Chapter 11). Also, while viruses are generally considered to be smaller in both size and gene content than cells, some viruses do not fit into this paradigm. Giant viruses of protozoa are known that possess genomes larger than those of some bacteria. This is in sharp contrast to a common virus such as influenza A virus, which contains only seven genes, and some viruses have even fewer genes than this.

Viruses can be classified on the basis of the hosts they infect as well as by their genome structure (► Section 11.1). Thus, we have bacterial viruses, archaeal viruses, animal viruses, plant viruses, protozoan viruses, and so on (Figure 5.1). Bacterial viruses are called **bacteriophages** (or simply *phage* for short) and have been intensively studied as model systems for the molecular biology and genetics of virus replication. In this chapter we will use bacteriophages many times to illustrate basic viral principles. Indeed, many of the key tenets of virology were discovered in studies of bacteriophages and subsequently applied to viruses of higher organisms.

Because of their frequent medical and agricultural importance, disease-causing viruses have been extensively studied. However, not all viruses have negative effects on their hosts, and in some cases viruses are even beneficial to their hosts! For example, when *Arabidopsis* plants are infected with plum pox virus, the plant's tolerance to drought increases due to virally induced production of the plant growth factor salicylic acid (Figure 5.3). In the rosy apple aphid, infection by an insect densovirus results in both decreased aphid size and offspring numbers. However, despite these negative effects, the infection also results in the formation of wings, structures not produced in uninfected aphids. Wing formation benefits the virus-infected aphid as it allows it to fly to new apple trees to feed on. And finally, in humans, although hepatitis G virus rarely causes symptoms in healthy adults, humans coinfecting with both HIV (human immunodeficiency virus) and hepatitis G virus benefit from the hepatitis G infection because it decreases the replication rate and infectivity of HIV.

With viruses being the most abundant entity on Earth, numerous other examples of positive host–virus interactions likely exist in nature. But coupled with these, of course, are the countless negative

interactions brought about by viral infection, and examples of these will unfold in many places throughout this book.

- How does a virus differ from a cell?
- Why does a virus need a host cell?
- Compared with cells, what is unusual about viral genomes?

5.2 Structure of the Virion

Virions come in many shapes and sizes (Figure 5.1). Most viruses are smaller than prokaryotic cells, ranging in size from 0.02 to 0.3 μm (20–300 nanometers, nm). While the human smallpox virus is about the size of the smallest known bacterial cells (200 nm in diameter, $\blacktriangleleft$ Section 1.3), giant viruses exist. Viruses such as the *Pandoravirus*, which has been isolated from protozoa, can rival the size of bacterial cells at over 1 μm in length (Figure 5.4). Poliovirus, one of the smallest viruses at only 28 nm in diameter, is on the opposite end of the size spectrum. This tiny virus is about the size of a ribosome, the cell's protein-synthesizing machine ($\blacktriangleleft$ Section 1.2).

Virion Structure

The structures of virions are quite diverse, varying widely in size, shape, and chemical composition. The nucleic acid of a virion is always surrounded by its capsid (Figure 5.2). The capsid is composed of a number of individual protein molecules called **capsomeres** that are often arranged in a precise and highly repetitive pattern around the nucleic acid.

The small size of most viral genomes restricts the number of distinct viral proteins that can be encoded. As a consequence, a few viruses have only a single kind of protein in their capsid. An example is the well-studied tobacco mosaic virus (TMV), which causes disease in tobacco, tomato, and related plants. TMV is a virus in which the 2130 copies of the capsomere protein are arranged in a helix with dimensions of 18×300 nm (Figure 5.5).

The information required for the proper folding and assembly of viral proteins into capsomeres and subsequently into capsids is often embedded within the amino acid sequence of the viral

Figure 5.4 The giant and asymmetrical *Pandoravirus*. (a) Scanning electron micrograph of *Pandoravirus* in a sewage sample from Mergulhão, Brazil. (b) Color-enhanced transmission electron micrograph of *Pandoravirus*. The virion is $\sim 1.2 \mu\text{m}$ long and the arrow indicates apical pore.

proteins themselves. When this is the case, virion assembly is a spontaneous process and is called *self-assembly*. However, some virus proteins and structures require assistance from the host cell's folding proteins for proper folding and assembly. For example, the capsid protein of bacteriophage lambda (Section 5.6) requires assistance from an *Escherichia coli* host cell's chaperone protein in order to fold into its active conformation.

Virus Symmetry

Many virions are highly symmetric structures. When a symmetric structure is rotated around an axis, the same form is seen again after a certain number of degrees of rotation. Two kinds of symmetry are recognized in viruses, which correspond to the two primary viral shapes, rod and spherical. Rod-shaped viruses have *helical* symmetry while spherical viruses have *icosahedral* symmetry. A typical virus with helical symmetry is TMV (Figure 5.5). The lengths of helical viruses are determined by the length of the nucleic acid, and the width of the helical virion is determined by the size and packaging of the capsomeres.

Viruses with icosahedral symmetry contain 20 triangular faces and 12 vertices and are roughly spherical in shape (Figure 5.6a). Axes of symmetry divide the icosahedron into 5, 3, or 2 segments of identical size and shape (Figure 5.6b). Icosahedral symmetry is the most efficient arrangement of subunits in a closed shell because it requires the smallest number of capsomeres to build the shell. The simplest arrangement of capsomeres is 3 per triangular face, for a total of 60 capsomeres per virion. However, most viruses have more nucleic

Figure 5.6 Icosahedral symmetry. (a) Model of an icosahedron. (b) Three views of an icosahedron showing 5-, 3-, or 2-fold symmetry. (c) Electron micrograph of human papillomavirus, a virus with 5-fold icosahedral symmetry. The virion is about 55 nm in diameter. (d) Three-dimensional reconstruction of human papillomavirus; a virion contains 360 units arranged in 72 pentacapsomeres, each consisting of 2 separate proteins.

acid than can be packed into a shell made from 60 capsomeres and so viruses with some multiple of 60 capsomeres, such as 180, 240, or 360, are more common. The capsid of the human papillomavirus (Figure 5.6c), for example, consists of 360 capsomeres, with the capsomeres arranged into 72 clusters of 5 each (Figure 5.6d).

The structure of some viruses is highly complex, with the virion consisting of several parts each displaying its own shape and symmetry. The most structurally complex of all viruses are the head-plus-tail bacteriophages such as phage T4 that infects *Escherichia coli*. A T4 virion consists of an icosahedral head plus a helical tail (Figure 5.7). Some large viruses that infect eukaryotes, especially the giant viruses of the protozoan *Acanthamoeba*, are also structurally complex. Quite distinct from the head-plus-tail bacteriophages are *Pandoravirus* and *Mimivirus*. *Pandoravirus* possesses an ovoid morphology and an apical pore (Figure 5.4), while *Mimivirus* has a five-pronged star feature called *stargate* (Figure 5.1 and see Figure 5.19b).

Enveloped Viruses

Enveloped viruses have a lipoprotein envelope surrounding the nucleocapsid (Figure 5.2). Most enveloped viruses (for example, Ebola, Figure 5.8a, b; see also Figure 5.21) use proteins on the virion's outer surface to attach to the cytoplasmic membrane and subsequently infect the cell. In contrast to the cells of humans and other animals, plant and bacterial cells are surrounded by a cell wall outside the cytoplasmic membrane, and thus few examples of enveloped viruses are known to infect these organisms. Typically, the *entire virion* enters an animal cell during infection, with the envelope, if present, assisting in the infection process by fusing with the

Figure 5.7 Structure of T4, a complex bacteriophage. Transmission electron micrograph of bacteriophage T4 of *Escherichia coli*. The tail components function in attachment of the virion to the host and injection of the nucleic acid (see Figure 5.15). The T4 head is about 85 nm in diameter.

host membrane. Enveloped viruses also exit more easily from animal cells. As they pass out of the host cell, they are draped in cytoplasmic membrane material. The viral envelope consists primarily of host cytoplasmic membrane, but some viral surface proteins (Figure 5.8a, b) also become embedded in the envelope as the virus passes out of the cell.

The viral envelope is important in infection, as it is the component of the virion that makes contact with the host cell. The specificity of infection by enveloped viruses and some aspects of their penetration are thus controlled in part by the biochemistry of their envelopes. The virus-specific envelope proteins are critical for both attachment of the virion to the host cell during infection and for release of the virion from the host cell after replication.

Besides an envelope, some viruses possess other structures important for infection. The giant *Mimivirus* and *Tupanvirus* that infect *Acanthamoeba* possess hairlike structures called *fibrils* on their capsid (Figure 5.9). These fibrils are made of a polymer similar to peptidoglycan (Section 2.3) and are believed to increase infection rates by attracting amoeba hosts that have fed on bacterial cells. Also facilitating infection are the apical pore and stargate features of *Pandoravirus* and *Mimivirus* mentioned earlier (Figures 5.4b, 5.1c, and see Figure 5.19b). These unique features act as portals, which open to release the viral genome once the virus is inside the host cell.

Enzymes inside Virions

Viruses do not carry out metabolic processes and are thus metabolically inert. Nonetheless, some viruses carry enzymes in their virions that play important roles in infection. For example, viruses that infect *Bacteria* and *Archaea* often only insert their genome into their host. Thus some bacteriophages contain an enzyme that resembles lysozyme (Section 2.3), which is used to make a small hole in the

Figure 5.8 Enveloped viruses. (a) Cryo-electron micrograph (◀ Section 1.10) of an Ebola virion. The virions are helical with a diameter of 80 nm. Parts a and b modified from Beniach, D.R., Melito, P.L., deVarenes, S.L., Hiebert, S.L., Rabb, M.J., Lamboo, L.L., Jones, S.M., Booth, T.F. 2012. *PLoS One* 7(1): e29608.

peptidoglycan layer of the bacterial cell to allow nucleic acid from the virion to get into the host cytoplasm. A similar protein is produced in the later stages of infection to lyse the host cell and release new virions. Some animal viruses also contain enzymes that aid in their release from the host. For example, influenza virus (Figure 5.8c) has envelope proteins called *neuraminidases* that destroy glycoproteins and glycolipids of animal cell connective tissue, thus liberating the virions (▶ Section 11.9).

Viruses with RNA genomes carry enzymes (RNA-dependent RNA polymerases called *RNA replicases*) in their virion that function to replicate and express the viral RNA genome. Such enzymes are necessary because host cells lack enzymes of any type that can make RNA from an RNA template. **Retroviruses**, such as HIV, are unusual animal viruses that convert their RNA genome to a DNA intermediate. Because this is another process that host cells cannot do, retroviral virions contain enzymes called *reverse transcriptase* (▶ Section 11.11).

Although we will see that most viruses do not need to carry special enzymes in their virions, those that do absolutely require them for successful infection and replication. The genes that encode these special enzymes are carried by the virus genome and are expressed in the infection cycle at just the right time to facilitate host infectivity and successful replication of the virus.

Check Your Understanding

- Distinguish between a capsid and a capsomere. What is a common symmetry for spherical viruses?
- What is the difference between a naked virus and an enveloped virus?
- What kinds of enzymes can be found within the virions of RNA viruses? Why are they there?

5.3 Culturing, Detecting, and Counting Viruses

Host cells need to be growing in order for viruses to multiply in them; dead cells cannot produce viruses. While not all viruses kill their host cell, this section focuses on lytic bacteriophages because the culturing and detection of these viruses are easier to describe and visualize.

To culture a bacteriophage such as T4 of *Escherichia coli*, pure cultures of the bacterial host are either inoculated in liquid medium or spread as “lawns” on the surface of agar plates and then inoculated with a virus suspension. By contrast, animal and plant viruses are cultivated in *tissue cultures*. For animal viruses, the cells are obtained from an animal organ and grown in sterile glass or plastic vessels containing an appropriate culture medium (see Figure 5.11). Animal

tissue culture media are often highly complex, containing a wide assortment of nutrients including blood serum and other highly nutritious substances to feed the animal cells as well as antimicrobial agents to prevent bacterial contamination. For plant tissue cultures, a hairy root-based system is often used to easily propagate viruses, as the infected roots can grow in a liquid medium.

Detecting and Counting Viruses: The Plaque Assay

A viral suspension can be quantified to estimate the number of infectious virions present per volume of fluid, a quantity called the **titer**.

This is typically done using a *plaque assay*. When a lytic virus infects host cells growing on a flat surface, a zone of cell lysis called a **plaque** forms and appears as a clear area in the lawn of host cells (Figure 5.10).

With bacteriophages, plaques may be obtained when virions are mixed into a small volume of molten agar containing host bacteria that is spread on the surface of an agar medium (Figure 5.10a). During incubation, the bacteria grow and form a turbid layer (lawn) that is visible to the naked eye. However, wherever a successful viral infection has occurred, cells are lysed, forming a plaque (Figure 5.10b). By counting the number of plaques, one can calculate the titer of the virus sample. The titer is typically expressed as the number of “plaque-forming units” per milliliter rather than an absolute viral number because of variations in plating efficiency, to be described next. However, when considering the plaque assay as a method, one should note that quantifying viruses by obtaining their titer is analogous to the counting of bacterial colonies that have formed on the surface of an agar plate from spreading a bacterial cell suspension (“plate count methods,” ◀ Section 4.4).

In order to replicate animal viruses that kill their host cell, a tissue culture is grown, and a diluted virus suspension is overlaid on it. As for bacterial viruses, plaques are revealed as cleared zones in the tissue culture cell layer, and from the number of plaques produced, an estimate of the animal virus titer can be made (Figure 5.11). Viral titer is much harder to determine in plants, as plaques do not form in plant tissue culture. Instead viruses must be purified from the plant tissue and enumerated microscopically or through serological or molecular methods that specifically target viral proteins (Chapter 29).

Plating Efficiency in Estimates of Viral Titers

The concept of *plating efficiency* is important in quantitative virology for all virus types. In any given viral preparation, the number of plaque-forming units is always lower than actual counts of viral particles made microscopically (using an electron microscope). This is because the efficiency with which virions infect host cells is rarely 100% and may often be considerably less. Virions that fail to infect may have assembled incompletely during the maturation process, may contain defective genomes, or may have suffered a spontaneous mutation that prevents them from attaching or otherwise properly replicating. Alternatively, a low plating efficiency may mean that viral growth conditions were not optimal, host viability was low, or that some virions were damaged by handling or storage conditions.

Although plating efficiencies of bacterial viruses can often be higher than 50%, with many animal viruses it may be much lower, 0.1% or 1%. Knowledge of plating efficiency is useful in cultivating viruses because it allows the investigator to estimate what a titer needs to be to yield a certain number of plaques. If the titer is extremely low, the viral suspension may need to be concentrated by centrifugation or filtration before being used to infect host cells. This is especially true of animal viruses, as the costs of growing and maintaining tissue cultures can be significant.

Infected cells begin to grow but then are lysed, forming plaques in the lawn. (b) Plaques (about 1–2 mm in diameter) formed by bacteriophage T4.

Figure 5.11 Animal cell cultures and viral plaques. The stained monolayer of animal cells support replication of the virus, and lysed cells result in plaques.

II • Overview of the Viral Replication Cycle

Following viral infection of a host cell, new virions are produced by the host as directed by the viral genome. Some aspects of viral infection differ between prokaryotic and eukaryotic cells, but in both cell types, lytic and long-term relationships are possible depending on the virus.

For a virus to replicate, it must induce a living host cell to synthesize all the essential components needed to make new virions. Because of these biosynthetic and energy requirements, dead host cells cannot replicate viruses. During an active viral infection, viral

components are assembled into new virions that are released from the cell. Although replication steps are similar in most viruses, a major difference between viral infection of a *prokaryotic* cell and viral infection of a *eukaryotic* cell surrounds the initial step in infection. In cells of *Bacteria* and those *Archaea* in which the infection process has been studied, only the viral nucleic acid enters the host cell. By contrast, in plant and animal cells the entire virion is taken up. Despite this key difference, the replication of bacterial viruses has been extremely well studied and so we use them here as a model of viral replication events.

5.4 Steps in the Replication Cycle

A cell that supports the complete replication cycle of a virus is said to be *permissive* for that virus. In a permissive host, the viral replication cycle can be divided into five steps (Figure 5.12):

1. *Attachment* (adsorption) of the virion to the host cell
2. *Penetration* (entry, injection) of the virion nucleic acid into the host cell
3. *Synthesis* of virus nucleic acid and protein by host cell machinery as redirected by the virus
4. *Assembly* of capsids and *packaging* of viral genomes into new virions
5. *Release* of new virions from the cell

The growth response during virus replication is graphically illustrated in Figure 5.13. The response takes the form of a *one-step growth curve*, so named because a time course of virion numbers in the culture medium shows essentially no increase during the replication cycle until cells burst and release their newly synthesized virions. In the first few minutes after infection, the virus enters the *eclipse* phase, during

Figure 5.12 The replication cycle of a lytic bacterial virus. The virions and cells are not drawn to scale. The burst size can be a hundred or more virions per cell depending on the virus and the host cell.

which the viral genome and proteins will be replicated and produced, respectively. Once attached to a permissive host cell, a virion is no longer available to infect another cell. This is followed by the entry of viral nucleic acid into the host cell (Figure 5.12). If the infected cell breaks open at this point, the virion no longer exists as an infectious entity since the viral genome is no longer inside its capsid.

The *maturation* phase (Figure 5.13) begins as newly synthesized viral genomes become packaged inside their capsids. During the maturation phase, the number of infectious virions inside the host cell rises dramatically. However, the new virions still cannot be detected in a plaque assay unless the cells are artificially lysed to release them. Because newly assembled virions are not yet present outside the cell, the eclipse and early maturation periods together comprise the *latent period* of viral infection (Figure 5.13).

At the end of maturation, mature virions are released, either as a result of cell lysis or by budding or excretion, depending on the virus. The number of virions released per cell, called the *burst size*, varies with the particular virus and the particular host cell, and can range from a few to a few thousand. The duration of the virus replication cycle also varies, from 20–60 min (in many bacterial viruses) to 8–40 h (in most animal viruses).

In Sections 5.5 and 5.6 we use a specific example to revisit these stages of the virus replication cycle and examine each in more detail.

Check Your Understanding

- What is packaged into capsids during maturation?
- Explain the term burst size.
- Why is the latent period so named?

5.5 Bacteriophage T4: A Model Lytic Virus

Much of our understanding of *lytic* virus replication comes from the study of bacteriophages that infect *Escherichia coli*. Here we focus on one, bacteriophage T4 (Figure 5.7), as our model for reviewing the individual stages of the lytic virus life cycle in more detail. The study of bacteriophage T4 has contributed to many of the paradigms of modern genetics and molecular biology such as gene structure, the nature of the genetic code, and the discovery of mRNA (Chapter 6).

Attachment and Entry of Bacteriophage T4

The early steps in the life cycle of any bacteriophage are attachment to the surface of its host cell followed by penetration of the host cell outer layer(s) and entry of the viral genome into the cell (Figure 5.12).

A major factor in host specificity of a virus is *attachment*. The virion itself has one or more proteins on its external surface that interact with specific components called *receptors* on the host cell surface. In the absence of its specific receptor, the virus cannot attach to the cell and hence cannot infect. Moreover, if the receptor is altered, for example by mutation, the host may become resistant to virus infection. The host range of a given virus is thus to a major extent determined by the presence of a suitable receptor that the virus can recognize and attach to.

Viral receptors are surface components of the host, such as proteins, carbohydrates, glycoproteins, lipids, or lipoproteins, or cell structures made from these macromolecules (Figure 5.14). The receptors carry out normal functions for the cell; for example, the receptor for phage T1 is an iron-uptake protein (Figure 5.14) and that for bacteriophage lambda functions in maltose uptake. Carbohydrates specific to the lipopolysaccharide (LPS) outer membrane of *Escherichia coli* (◀ Section 2.4) are the receptors recognized by bacteriophage T4 (Figure 5.14). Appendages that project from the cell surface, such as flagella and pili, are also common receptors for bacterial viruses. Small icosahedral viruses often bind to the side of these structures (◀ Figure 2.18), whereas filamentous bacteriophages typically bind at the tip, such as on the pilus (Figure 5.14).

Figure 5.13 One-step growth curve of virus replication. Following adsorption, infectious virions cannot be detected in the growth medium, a phenomenon called *eclipse*. During the latent period, which includes the eclipse and early maturation phases, viral nucleic acid replicates and protein synthesis occurs. During the maturation period, virus nucleic acid and protein are assembled into mature virions and then released.

Figure 5.14 Bacteriophage receptors. Examples of the cell receptor sites used by different bacteriophages that infect *Escherichia coli*.

Regardless of the receptor used, however, once attachment has occurred, the stage is set for viral infection.

Penetration

Attachment of a virus to its host cell causes changes to both the virus and the host cell surface that result in penetration. Bacteriophages abandon their capsid outside the cell and only the viral genome reaches the cytoplasm. However, entry of the viral genome into a host cell only results in virus replication if the viral genome can be read. Consequently, for the replication of some viruses, for example RNA viruses, specific viral proteins must enter the host cell along with the viral genome (Section 5.2).

The most intricate viral penetration mechanisms belong to the tailed bacteriophages. Bacteriophage T4 consists of an icosahedral head, within which the viral linear double-stranded DNA is folded, and a long, complex tail, which ends in a series of tail fibers and tail pins that contact the cell surface (Figure 5.7). Phage T4 virions first attach to *Escherichia coli* cells using their tail fibers (Figure 5.15). The ends of the tail fibers interact specifically with polysaccharides in the cell's LPS layer and then the tail fibers retract, allowing the tail itself to contact the cell wall via the tail pins. The activity of T4 lysozyme then forms a small pore in the peptidoglycan layer and the tail sheath contracts. When this occurs, the T4 genome enters the cytoplasm of the cell through a tail tube in a fashion resembling that of injection by a syringe. By contrast, the T4 capsid remains outside the cell (Figure 5.15). DNA inside bacteriophage heads is under high pressure, and because the interior of a bacterial cell is also under pressure from osmotic forces, the phage DNA injection process takes several minutes to complete.

Once a bacteriophage injects its genome into a host cell, a productive infection is not absolutely ensured. Although they lack the immune systems of animals (Chapters 26 and 27), *Bacteria* and *Archaea* possess several weapons to protect against viral attack. Toxin–antitoxin modules (► Section 8.12) and an antiviral system called CRISPR (► Section 9.12) are two of these mechanisms. Additionally, *Bacteria* and *Archaea* can destroy double-stranded viral DNA through the activity of *restriction endonucleases*, enzymes that cleave foreign DNA at specific sites (► Section 12.2). Although host restriction systems confer significant protection from viral attack, some DNA viruses have overcome host restriction by modifying their own

genome so it is no longer subject to restriction enzyme attack.

Production of T4 Virions and Release

Once the T4 genome has successfully entered and been retained in a permissive host cell, the process of new virion synthesis begins. In less than half an hour, the process culminates in the release of new virions from the lysed cell. The major events are summarized in Figure 5.16.

Within a minute after the T4 genome enters the host cytoplasm, the synthesis of host-

specific proteins ceases and production of phage-specific proteins begins, thus inhibiting normal host growth. The T4 genome encodes three major sets of proteins called **early proteins**, **middle proteins**, and **late proteins**, the terms referring to the general order of their

Bo Hun, Jun Liu, and Ian Molleux

Figure 5.15 Attachment and infection of an *Escherichia coli* cell by bacteriophage T4. The three transmission electron tomographs and the art beneath each depict (left to right) the initial attachment of a T4 virion to the cell outer membrane by tail fiber interactions with lipopolysaccharide (LPS); contact of the cell wall by the tail pins; and contraction of the tail sheath and injection of the T4 genome. The tail tube penetrates the outer membrane, and T4 lysozyme digests a small opening through the *E. coli* cell peptidoglycan layer.

Figure 5.16 Time course of events in phage T4 infection. Following injection of DNA, early and middle mRNAs are produced that encode proteins needed for DNA replication. Following injection of DNA, early and middle proteins needed for DNA replication are produced. Late proteins are virion structural proteins and T4 lysozyme, which is needed to lyse the cell and release new virions.

appearance in the cell. Early proteins include enzymes for the production of T4 genome copies and proteins that modify host enzymes to express viral genes. This viral takeover of the host cell results in replication of the 170-kilobase T4 genome within 4 minutes of infection (we save the details of T4 genome replication for Chapter 11). By contrast, middle and late proteins include additional proteins that modify host enzymes, and virion structural and release proteins. These include, in particular, viral head and tail proteins and the enzymes required to liberate new virions from the cell (Figure 5.16).

Once viral head proteins are made, the bacteriophage T4 DNA genome is forcibly pumped into a preassembled capsid using an energy-linked packaging motor. The motor components are encoded

by viral genes, but host cell metabolism is needed to produce the proteins and supply the ATP required for the pumping process. The packaging process can be divided into three stages (Figure 5.17a). First, precursors of the bacteriophage head called *proheads* are assembled but remain empty of DNA. Proheads contain temporary “scaffolding proteins” as well as head structural proteins. Second, a packaging motor is assembled at the opening to the prohead (Figure 5.17b). The T4 DNA genome is then pumped into the prohead under pressure using ATP as the driving force. The prohead expands when pressurized by the entering DNA, and the scaffolding proteins are simultaneously discarded. Third, the packaging motor itself is discarded and the capsid head is sealed.

Figure 5.17a
Packaging of
DNA into a T4
phage head

Figure 5.17 Packaging of DNA into a T4 phage head. A T4 virion consists of a head, tail, collar, and various attachment structures (Figure 5.7). Assembly of the T4 virion requires the packaging of viral DNA into the phage head. (a) Proheads are assembled from capsid and portal proteins, both of which remain in the mature virion. As the head fills with DNA (driven by the energy released from ATP hydrolysis), it expands and becomes more angular. Once the head is filled, the packaging motor detaches and the tail components are added. (b) Cryo-electron micrograph reconstruction of the T4 prohead and packaging motor. The blowup shows proteins within the motor and the prohead and their contact with DNA.

After the head has been filled, the T4 tail, tail fibers, and the other components of the virion are added, primarily by spontaneous reactions or self-assembly (Figure 5.16). The phage genome encodes a pair of very late enzymes that combine to breach the two major barriers to virion release: the host cytoplasmic membrane and peptidoglycan layer. Once these structures are compromised, the cell breaks open by osmotic lysis and the newly synthesized virions are released. After each replication cycle, which takes only about 25 min (Figure 5.16), over 100 new virions are released from each host cell (the *burst size*, Section 5.4), and these are now free to infect neighboring host cells.

Check Your Understanding

- How does attachment contribute to virus–host specificity?
- Why does phage T4 need a lysozyme-like protein in order to infect its host, and what part of T4 enters the host cytoplasm?
- What is required to package the T4 genome into its phage head?

5.6 Temperate Bacteriophages and Lysogeny

Bacteriophage T4 is a **virulent virus** and once infection begins, it proceeds to kill its host through lysis. However, some double-stranded DNA bacterial viruses, although capable of a virulent cycle, can also infect their host and establish a long-term stable relationship. Such a virus is called a **temperate virus**.

Temperate viruses can enter into a state called **lysogeny**. In this state, very few viral proteins are produced; instead, the virus genome is replicated in synchrony with the host chromosome and passed to daughter cells at cell division. A cell that harbors a temperate virus is therefore called a **lysogen**. While growth of a lysogen is controlled by its local environment and nutritional profile, the lysogenic state may confer new genetic properties—a condition called *lysogenic conversion*. We will see several examples in later chapters of pathogenic bacteria whose virulence (ability to cause disease) is at least in part linked to a lysogenic bacteriophage.

Two well-characterized temperate bacteriophages are lambda and P1. The life cycle of a temperate bacteriophage is shown in Figure 5.18. During lysogeny, the temperate virus genome is often integrated into the bacterial chromosome. The viral DNA, now called a **prophage**, replicates along with the host cell as long as the genes that activate the phage virulent pathway are repressed.

Maintenance of the lysogenic state is due to a phage-encoded *repressor protein*. Normally, this repressor is maintained at a low level in the host cell. However, if the phage repressor is inactivated or if its synthesis is in some way prevented, the prophage can be induced to switch to the lytic stage. This process is called *induction*. When induction occurs, the viral DNA is excised and phage early, middle, and late proteins are produced similarly to the process described for T4 phage (Section 5.5 and Figure 5.16). New virions are then produced, and the host cell is lysed (Figure 5.18). Various cell stress conditions, especially damage to host cell DNA, can induce a prophage to enter the lytic pathway. In contrast to this process, the viral “decision” to proceed to lysogeny or to the lytic pathway upon initial viral infection is another matter altogether, and has been particularly well studied in bacteriophage lambda. We explore this rather intricate story in Chapter 11.

Figure 5.18 Consequences of infection by a temperate bacteriophage. The alternatives upon infection are replication and release of mature virions (lysis) or lysogeny, often by integration of the virus DNA into the host DNA, as shown here. The lysogen can be induced to produce mature virions and lyse.

Consequences of infection by a temperate bacteriophage

We finish our introduction to the viral world by briefly considering viruses that infect eukaryotic hosts, both plant and animal. As we will see in Chapters 29–33, many of the most notorious scourges of humankind are of viral origin (see Table 5.1 for some examples).

Check Your Understanding

- What is a lysogen and what is a prophage?
- How do temperate viruses differ from virulent (lytic) viruses?
- When considering lysogeny, what occurs during the process of induction?

5.7 An Overview of Viruses of Eukaryotes

The major tenets of virology—presence of a capsid to carry the viral DNA or RNA genome, infection and takeover of host metabolic processes, and assembly and release from the cell—are universal, regardless of the nature of the host. Like bacterial viruses, eukaryotic viruses are classified by their genomes (Table 5.1). However, three key differences between bacterial and eukaryotic viruses are that (1) the entire virion of eukaryotic viruses (rather than just the nucleic acid)

TABLE 5.1 Representative viral diseases of humans and plants			
Disease or host	Virus	Genome DNA or RNA ^a	Size ^b
Human viruses			
Cold sores/genital herpes	Herpes simplex	dsDNA	152,000
Smallpox	Variola major	dsDNA	190,000
Influenza	Influenza A virus	ssRNA	13,600
Ebola hemorrhagic fever	Ebola virus	ssRNA	19,000
Severe acute respiratory syndrome (SARS)	SARS virus	ssRNA	29,800
Infant diarrhea	Rotavirus	dsRNA	18,600
Acquired immunodeficiency syndrome (AIDS)	Human immunodeficiency virus (HIV)	ssRNA/dsDNA (a retrovirus)	9,700
Plant viruses			
Cauliflower, turnip, cabbage	Cauliflower mosaic virus	dsDNA	8,000
Cassava	African cassava virus	ssDNA	5,500
Strawberry	Strawberry crinkle virus	ssRNA	14,500

Rice, maize, wheat, barley	Rice black streaked dwarf virus	dsRNA	29,100

^ass, single-stranded; ds, double-stranded.
^bIn bases (ss genomes) or base pairs (ds genomes). These viral genomes have been sequenced and thus their lengths are known precisely. However, the sequence and length often vary slightly among different isolates of the same virus. Hence, the genome sizes listed here have been rounded off in all cases.

enters the host cell, (2) eukaryotic cells contain a nucleus, where many (but not all) viruses replicate, and (3) in some eukaryotic cells, membrane-bound “viral factories,” also known as *viroplasm*s, form to increase the rate of virion assembly and protect the process from host defenses (Figure 5.19). We explore some aspects of animal and plant viruses here.

Viral Infection of Animal Cells

While a large number of animal viruses exist (Chapter 11), most animal viruses that have been studied in detail are those that can replicate in cell cultures (Section 5.3 and Figure 5.11). To initiate infection, animal viruses also bind to specific host cell receptors. These virus receptors are typically animal cell surface proteins used in cell–cell contact or that function in the immune system. For example, the receptors for poliovirus and for HIV (the virus that causes AIDS) are normally used in intercellular communication between human cells. In multicellular organisms, cells in different tissues or organs often express different proteins on their cell surfaces. Consequently, viruses that infect animals often infect only certain tissues. For example, viruses that cause the common cold infect only cells of the upper respiratory tract.

Once an animal virus is bound to a receptor, its entry into a host cell generally occurs by fusion with the cytoplasmic membrane or by endocytosis (Figure 5.20). After entry into the cell, animal viruses must eventually lose their outer coat to deliver their genomes to the cytosol. Some enveloped animal viruses are uncoated at the host cytoplasmic membrane, releasing the nucleocapsid into the cytoplasm, while naked and enveloped animal viruses that enter via endocytosis are uncoated in the host cytoplasm. If the viral genome is DNA, the genome passes through the nuclear membrane to the nucleus for replication. Conversely, the genomes of most RNA-based

viruses are replicated or converted to DNA by viral enzymes within the nucleocapsid. We will focus on the unique mode of replication of retroviruses, a special class of highly unusual RNA animal viruses with significant medical implications, in Chapter 11.

Animal Virion Assembly and Infection Outcomes

Virion assembly and morphogenesis occurs once viral nucleocapsids have been produced by the host’s machinery. After viral genome copies are packaged within their outer coat, many animal viruses must be enveloped. This typically occurs when the virion exits the animal cell through cell lysis or a process called *budding* (Figure 5.21). During this process the virus may pick up part of the cell’s cytoplasmic membrane as it exits the cell and use it as part of the viral envelope.

Unlike a bacteriophage infection, in which one of only *two* outcomes—lysis or lysogeny—is possible depending on the virus, other events are possible in an animal virus infection. If an animal virus initially evades the immune system, animal viruses can catalyze at least four different outcomes (Figure 5.22). A *virulent infection* (or lytic infection) results in lysis of the host cell; this is the most common outcome. By contrast, in a *latent infection*, the viral DNA exists in the host’s genome as a **provirus** from a process similar to that described for lysogeny (Section 5.6) and virions are not produced; this leaves the host cell unharmed unless and until an event triggers the virulent pathway. With some enveloped animal viruses, release of virions may be slow, and the host cell may not be lysed (and thus not killed); instead the host cell continues to grow and produce more virions. Such infections are called *persistent infections*. Finally, certain animal viruses can convert a normal cell into a tumor cell, a process called *transformation* (Figure 5.22). Some human cancer viruses are capable of such activity (► Section 11.7), although the vast majority of cancers are not of viral origin.

(b) Scanning electron micrograph of a viral factory with APMV. Note prominent stargate feature (Figure 5.1c).

Viral Infection of Plant Cells

Plant viruses share many traits with animal viruses; for example, most have RNA genomes, the complete virion enters the host cell, and viral factories form in infected cells (Figure 5.19). However, three major differences between animal and plant viruses are that (1) many plant viruses have a wide host range (Table 5.1), with viruses such as the cucumber mosaic virus able to infect over 1200 species of plants; (2) most plant viruses are not enveloped; and (3) plant virus transmission to host cells occurs in a different manner due to both the immobility of plants and the rigidity of the cell wall, a structure that is absent from animal cells.

While animal viruses often enter host cells by endocytosis, plant cells contain a protective cell wall preventing such entry. Thus, viruses enter new plant hosts through wounds in the plant tissue or through penetration of the plant cell wall by insects, nematodes, or fungi. In fact, many plant viruses can attach to the mouthparts of plant pests or even propagate in the guts of such pests. Pests that are able to transfer viruses to other types of host cells are called *vectors*.

Once the virion has successfully entered a plant cell, the capsid is removed, the genome is replicated in the nucleus or viral factory, and new virions are assembled (Figure 5.23). For infection of other cells within the plant to occur, the viral genome often encodes special movement proteins that help viruses travel through small channels, called plasmodesmata, that connect plant cells. This movement can lead to the viruses entering the vascular system and infecting the

Figure 5.22 Possible effects of animal virus infection of host cells. Most animal viruses are lytic, and only a very few are known to cause cells to transform and become cancerous.

entire plant (Figure 5.23). Vectors that feed on this infected plant can then transfer the virus to healthy plants, repeating the infection cycle and causing widespread crop damage.

As exemplified by the viruses we have considered in this chapter, viruses are truly fascinating microbes. On the one hand, the multiplication of any virus is completely dependent on the growth and activities of its host cell; on the other hand, viruses can control the growth, genetic properties, and very survival of their hosts. We revisit the viruses in Chapter 11 with a focus on viral genomics as the criterion by which we reveal the enormous genetic diversity of these important microbes. Although our discussion of viruses in this chapter has covered some of their remarkable characteristics, we have only scratched the surface.

Check Your Understanding

- Contrast the ways in which animal and bacterial viruses enter their hosts.
- What is the difference between a persistent and a latent viral infection?
- How does viral infection of plants differ from viral infection of animals?

Figure 5.23 Viral infection of plants. Unlike infecting an animal, where viruses can readily attach and fuse with the animal cell's cytoplasmic membrane, to infect a plant, viruses have to traverse the plant cell wall that may be thick. Virions rely on some form of surface damage to the plant, entering a plant cell through a wound or insect bite. Infection leads to viral multiplication and the production of viral-encoded movement proteins, which allow for transfer of viruses to adjacent plant cells through plasmodesmata. The entire plant can be infected once the virus enters the vascular system.

CHAPTER REVIEW

I • The Nature of Viruses

- 5.1** A virus is an obligate intracellular parasite that requires a suitable host cell for replication. A virion is the extracellular form of a virus and contains either an RNA or a DNA genome inside a protein shell. Once the virus is inside the cell, the viral nucleic acid, and sometimes viral enzymes, redirects host metabolism to support virus multiplication. Viruses are classified by the characteristics of their genome and hosts. Bacteriophages infect bacterial cells and are model systems for studying viruses.

Q Briefly describe the two approaches a bacteriophage can take to trigger an infection once inside its host cell.

- 5.2** In the virion of a naked virus, only nucleic acid and protein are present; the entire unit is called the nucleocapsid. Enveloped viruses have one or more lipoprotein layers surrounding the nucleocapsid. The nucleocapsid is often arranged in a symmetric fashion, with the icosahedron being a common morphology. Some viruses also possess structures that assist with the infection process. Although virus particles are metabolically inert, some viruses have one or more key enzymes within their virion that carry out processes that the host cannot.

Q Where does the envelope surrounding animal viruses originate?

- 5.3** Viruses can replicate only in their correct host cells. Bacterial viruses have proved useful as model systems because their host cells are easy to grow and manipulate in culture. Many animal viruses can be grown in cultured animal cells. Viruses can be quantified (titered) by a plaque assay. Plaques are clearings that develop on lawns of host cells, and in analogy to bacterial colonies, they arise from the viral infection of a single cell.

Q Draw a diagram of the one-step growth curve of virus replication, and briefly explain why the growth curve differs from a typical bacterial growth curve.

II • Overview of the Viral Replication Cycle

- 5.4** The virus replication cycle can be divided into five major stages: attachment (adsorption), penetration (uptake of the entire virion or injection of the nucleic acid only), protein

and nucleic acid synthesis, assembly and packaging, and virion release.

Q Why does the viral one-step growth curve differ in shape from that of a bacterial growth curve?

- 5.5** The attachment of a virion to a host cell is a highly specific process. Recognition proteins on the virus recognize specific receptors on the host cell. Sometimes the entire virion enters the host cell, whereas in other cases, as with most bacteriophages, only the viral genome enters. After a T4 virion penetrates a host cell, its genome enters the cytoplasm and viral genes are expressed to redirect the host synthetic machinery to make viral nucleic acid and protein. Early viral genes encode viral genome replication events; middle and late viral genes encode structural proteins and capsid assembly. Once T4 components have been synthesized, new virions are assembled and released after lysis of the host cell.

Q What is required for a bacteriophage T4 virion to attach to an *Escherichia coli* cell? What host barriers must be broken before release of T4 virions from the host cell?

- 5.6** Some bacteriophages are temperate, meaning that they can initiate lytic events or integrate into the host genome as a prophage. Integration initiates a state called lysogeny in which the virus does not destroy the cell. If the lysogenic state goes through the process of induction, the viral infection switches to virulent (lytic). A well-studied lysogenic virus of *Escherichia coli* is phage lambda.

Q What kind of protein is required for bacteriophage lambda to maintain a lysogenic state?

- 5.7** There are eukaryotic viruses with all known modes of viral genome replication. This replication can occur in the nucleus or a compartment called a viroplasm. Many animal viruses are enveloped, picking up portions of host membrane as they leave the cell. Viral infection of animal host cells can result in cell lysis, but latent or persistent infections are also common, and a few animal viruses can cause cancer. In contrast, plant viruses are rarely enveloped and can often infect a wide range of plant, insect, nematode, and fungal species. These pests transfer the virion from one plant to another by puncturing through the rigid plant cell wall.

Q How do virions spread throughout the cells of a plant host? Why do plant viruses require host damage for infectivity?

APPLICATION QUESTIONS

1. What causes the viral plaques that appear on a bacterial lawn to stop growing larger?
2. What would happen if a prophage was not able to undergo the process of induction? How would this affect the virus and its host cell?

3. Under some conditions, it is possible to obtain nucleic acid-free protein coats (capsids) of certain viruses. Under the electron microscope, these capsids look very similar to complete

virions. What does this tell you about the role of the virus nucleic acid in the virus assembly process? Would you expect such particles to be infectious?

CHAPTER GLOSSARY

Bacteriophage a virus that infects bacterial cells

Capsid the protein shell that surrounds the genome of a virus particle

Capsomere the subunit of a virus capsid

Early protein a protein synthesized soon after viral infection and before replication of the viral genome

Enveloped in reference to a virus, having a lipoprotein membrane surrounding the virion

Host cell a cell inside which a virus replicates

Late protein a protein, typically a structural protein, synthesized late in viral infection

Lysogen a bacterium containing a prophage

Lysogeny a state in which the viral genome is replicated in step with the genome of the host

Lytic pathway the type of viral infection that leads to virus replication and destruction of the host cell

Middle protein a protein with either a structural or a catalytic function synthesized after the early proteins in a virus infection

Nucleocapsid the complex of nucleic acid and capsid (shell) proteins of a virus

Plaque a zone of lysis or growth inhibition caused by viral infection of a bacterial lawn or other culture of sensitive host cells

Prophage the lysogenic form of a bacteriophage (see *provirus*)

Provirus the genome of a temperate, or latent, animal virus when it is replicating in step with the host chromosome

Retrovirus a virus whose RNA genome is replicated via a DNA intermediate

Temperate virus a virus whose genome can replicate along with that of its host without causing cell death, in a state called lysogeny (bacterial viruses) or latency (animal viruses)

Titer the number of individual particles of a substance, such as antibodies or infectious virions, per unit volume of a solution

Virion the infectious virus particle; the viral genome surrounded by a protein coat and sometimes other layers

Virulent virus a virus that lyses, or kills, the host cell after infection

Virus a genetic element that contains either RNA or DNA surrounded by a protein capsid and that replicates only inside host cells

MICROBIOLOGYNOW

Injectisomes: *Salmonella*'s Mode of Attack

Salmonella is a genus of gram-negative *Bacteria* that causes salmonellosis in humans. Once *Salmonella* colonizes the intestines, the pathogen produces proteins called effectors to manipulate host epithelial cells and trigger disease symptoms. In fact, this pathogen delivers over 40 different effectors, many of which are toxins, directly into host epithelial cells during infection. How does *Salmonella* accomplish such an aggressive feat?

Salmonella possesses a secretion system known as type III that moves effectors all the way through its membranes and cell wall into a host cell. The inset in the photo here shows a cryo-electron tomograph of a type III secretion system. The machinery can be divided into three parts: bottom—a platform that resides inside the bacterial cytoplasm; middle—a basal body within the periplasm and an outer membrane-anchored base; and top—a protruding needle filament. Based on this syringe-like morphology, type III secretion systems have been termed “injectisomes.”

The actual injection of effector proteins into host cells

requires an orchestrated series of events that is triggered when the injectisome tip makes contact with the host cell, and the colored tomograph illustrates this cell-to-cell contact. Bacterial cell membranes and ribosomes are green, and a blue injectisome (white arrow) is shown making contact with the host cell membrane (red). Host cell actin filaments and ribosomes are depicted in orange and purple, respectively.

Injectisome contact does not actually stab a hole into the host cell as one might expect. Instead, the contact leads to the formation of a protein channel (not shown) that allows for the passage of the toxin proteins from one domain of life to the other. Injectisomes are deployed by several other pathogens including *Yersinia* (plague), *Shigella* (gastrointestinal distress), *Pseudomonas* (various infections), and *Chlamydia* (sexually transmitted infections), and thus the success of this structure in facilitating disease symptoms is readily apparent.

I • Molecular Biology and Genetic Elements

Genetic information flow is the hallmark of all cells, as the central dogma of cell biology is that DNA begets RNA begets protein. These processes are invariant in cells of all domains of life and can be initiated from many different DNA genetic elements, the chromosome being chief among them.

In Part I we examine the structure of DNA and the basic processes in genetic information flow and then move on to consider the various types of genetic elements. Part I lays the groundwork for a detailed consideration of DNA replication in prokaryotic cells (Part II) and the mechanisms behind RNA and protein synthesis (Parts III and IV).

6.1 DNA and Genetic Information Flow

An overview of the major macromolecules and processes of molecular biology is shown in **Figure 6.1a**. In addition, the functional unit

of genetic information is the **gene**, and genes make up parts of chromosomes or other large molecules known collectively as **genetic elements**; the total complement of genetic elements is the **genome**. Genetic information is embedded in the sequence of nucleotides in the nucleic acids **DNA** and **RNA**. DNA carries the cell's genetic blueprint while RNA, produced in transcription, carries a copy of this blueprint. One form of RNA called messenger RNA is converted by translation into defined amino acid sequences in proteins. Collectively, nucleic acids and proteins are called **informational macromolecules** (Figure 6.1a).

The monomers of nucleic acids are called **nucleotides** and so DNA and RNA are **polynucleotides**. A nucleotide has three components: a pentose sugar (either ribose in RNA or deoxyribose in DNA), a nitrogenous base, and a molecule of phosphate, PO_4^{3-} (Figure 6.1b). A **nucleoside** has a pentose sugar and a nitrogenous base but does not include a phosphate group. The nitrogenous bases in nucleic acids are either **pyrimidines** or **purines**. The purines guanine and adenine and the pyrimidine cytosine are present in both DNA and RNA, whereas the pyrimidines thymine and uracil are only present (with minor exceptions) in DNA and RNA, respectively (Figure 6.1c).

Properties of the Double Helix

The nucleic acid backbone is a polymer of alternating sugar and phosphate molecules, and nucleotides are linked by phosphate between the 3'-carbon of one sugar and the 5'-carbon of the next

Figure 6.1 Genetic information flow and the components of the nucleic acids. (a) An overview of the types of informational macromolecules. (b) Part of a DNA chain. The numbers on the sugar of the nucleotide contain a prime (') to differentiate them from the numbering on the rings of the nitrogen bases. In DNA, a hydrogen is present on the 2'-carbon of the

pentose sugar. In RNA, an OH group occupies this position (indicated by the red dashed circle). The nucleotides are linked by a phosphodiester bond. (c) The nitrogen bases of DNA and RNA and the specific pairing between cytosine (C) and guanine (G) and between thymine (T) and adenine (A) via hydrogen bonds. Uracil (U) instead of thymine is

present in RNA as indicated by the red dashed circle. Note the numbering system of the rings in that a pyrimidine base bonds through N-1 to the sugar-phosphate backbone and that a purine base bonds through N-9. Atoms that are found in the major groove of the double helix (see Figure 6.3) and that interact with proteins are highlighted in pink.

Figure 6.2 DNA structure. Complementary and antiparallel nature of DNA. Note that one chain ends in a 5'-phosphate group, whereas the other ends in a 3'-hydroxyl. The purple bases represent the pyrimidines cytosine (C) and thymine (T), and the yellow bases represent the purines adenine (A) and guanine (G).

sugar, the **phosphodiester bond** (Figure 6.1b, Figure 6.2). The **sequence** of nucleotides in a DNA or RNA molecule is its **primary structure** and encodes the genetic information. In cells, DNA is **double-stranded**, the strands being held together by hydrogen bonds between the bases in the two strands (Figure 6.1c). Specific base pairing, A with T and G with C, ensures that the two strands of DNA are **complementary** in base sequence, and this complementarity is essential for the faithful replication of the molecule. The two strands of the DNA molecule are also arranged in an **antiparallel** fashion; one strand runs 5' to 3' (top to bottom), whereas its complement runs 5' to 3' (bottom to top) (Figure 6.2).

The complementary and antiparallel strands of DNA are wrapped around each other to form a double helix (Figure 6.3). The helix naturally forms two distinct grooves, the **major groove** and the **minor groove**. Most proteins that interact specifically with DNA bind in the major groove, where space is abundant. Because the double helix is a regular structure, some atoms of each base are always exposed in the major groove (and some in the minor groove). These key regions of the DNA that are important in interactions with proteins can be seen in Figure 6.3, and the atoms of the major groove that interact with proteins are highlighted in pink in Figure 6.1c.

Figure 6.3 Arrangement of the DNA double helix. (a) A computer model of a short segment of DNA showing one of the sugar-phosphate backbones in blue-green and the other in light green. The pyrimidine bases are shown in purple and the purines in yellow. Note the locations of the major and minor grooves. One helical turn contains 10 base pairs. (b) Atomic force microscopy showing the biomolecular structure of a small piece of DNA. Note the locations of the major and minor grooves.

Size, Shape, and Supercoiling of DNA

The size of a DNA molecule is expressed as its total number of nucleotide base pairs. Thus, a double-stranded DNA molecule consisting of 1000 bases is one kilobase pair (kbp) of DNA. The bacterium *Escherichia coli* has about 4640 kbp (4.64 megabase pairs, Mbp) of DNA in its genome. If this molecule were extended linearly it would be several hundred times longer than the cell itself. To accommodate their genome, cells of *Bacteria* and *Archaea* must compact the DNA, and this is done by the process of **supercoiling** (Figure 6.4).

Supercoils are inserted or removed in DNA by enzymes called **topoisomerases**. The activity of supercoiling puts the DNA molecule under torsion (Figure 6.4), and DNA can be supercoiled in either a positive or a negative manner. Negative supercoiling results when the DNA is twisted about its axis in the opposite sense from the right-handed double helix and is the form found in most cells. In the *E. coli* chromosome, more than 100 supercoiled domains exist, each stabilized by specific proteins bound to the DNA. Inserting supercoils into DNA requires energy from ATP, whereas releasing supercoils does not. In *Bacteria* and most *Archaea*, the topoisomerase **DNA gyrase** inserts negative supercoils into DNA by making double-strand breaks (Figure 6.4a). As we see in Chapters 4 and 17, some

Figure 6.4 Supercoiled DNA and DNA gyrase. (a) Schematic showing the introduction of negative supercoiling into circular DNA by the activity of DNA gyrase (topoisomerase II), which makes double-strand breaks. (b) The double-stranded DNA in the bacterial chromosome is arranged not in one supercoil but in several supercoiled domains, as shown here. (c) Atomic force microscopy of the *Escherichia coli* nucleoid. (d) Simultaneous phase-contrast and fluorescence image of *E. coli* illustrating the location of the nucleoid within growing cells. Cells were treated with a fluorescent dye specific for DNA and the color was inverted to show the nucleoids as black.

Archaea live at very high temperatures—above the boiling point in some cases. These species have chromosomes that are *positively* (instead of negatively) supercoiled, and this genomic feature helps to maintain DNA structure (that is, it prevents the two strands from melting apart) at such high temperatures (► Section 17.13). Supercoiling is not a feature of eukaryotes since their genomic DNA is linear rather than circular. However, eukaryotic DNA must still be compacted, and this occurs when the DNA is highly wound around histone proteins.

Genes and the Steps in Biological Information Flow

Genetic information flow is a fundamental process in all cells and is the *central dogma of molecular biology* (Figure 6.1a and Figure 6.5). When genes are *expressed*, the genetic information encoded in DNA is transferred to ribonucleic acid (RNA). While several classes of RNA exist in cells, three main classes of RNA participate in protein synthesis. **Messenger RNAs (mRNAs)** are single-stranded molecules that carry the genetic information from DNA to the ribosome. **Transfer RNAs (tRNAs)** help convert the genetic information in the nucleotide sequences of RNA into a defined sequence of amino acids in proteins. **Ribosomal RNAs (rRNAs)** are important catalytic and structural components of the ribosome. The molecular processes

of genetic information flow can be divided into three stages (Figure 6.5):

1. **Replication.** During replication, the DNA double helix is duplicated. Replication is catalyzed by the enzyme *DNA polymerase*.
2. **Transcription.** The transfer of genetic information from DNA to RNA is called transcription. Transcription is catalyzed by the enzyme *RNA polymerase*.
3. **Translation.** The formation of a polypeptide using the genetic information transferred to mRNA by DNA is a process that occurs on the ribosome.

Many different RNA molecules can be transcribed from a relatively short region of the long DNA molecule. In eukaryotes, each gene is transcribed to yield a single mRNA, whereas a single mRNA molecule may encode several different proteins in *Bacteria* and *Archaea*. However, a linear correspondence exists between the base sequence of a gene and the amino acid sequence of a polypeptide, and as we will see, each group of *three bases* on an mRNA molecule encodes a single amino acid (Section 6.9).

Eukaryotes differ from *Bacteria* and *Archaea* in that the first two steps of the central dogma, replication and transcription (Figures 6.1 and 6.5), occur in the nucleus. Because ribosomes are not present in

Figure 6.5 Synthesis of the three types of informational macromolecules in the processes of replication (DNA → DNA), transcription (DNA → RNA), and translation (RNA → protein). Note that for any particular gene only one of the two strands of the DNA double helix is transcribed.

the nucleus, mRNAs as well as other RNAs must be transported outside of the nucleus for translation. By contrast, in prokaryotic cells, mRNAs do not have to be exported from an organelle to be translated. Because of this fundamental difference, transcription and translation in *Bacteria* and *Archaea* can occur simultaneously in a process known as *coupled transcription and translation* (Figure 6.6). During this process, a ribosome initiates translation of an mRNA before RNA polymerase has finished synthesizing it. This allows rapidly growing cells to produce proteins at a maximal rate and also allows the cell to rapidly adapt to changes in growth conditions by quickly expressing the new protein sets required.

While the central dogma of molecular biology (Figures 6.1a and 6.5) is invariant in *cells*, we will see later that some *viruses* (which are not cells, Section 1.4) violate the dogma in many interesting ways (Chapter 11). But for now we move on to consider the different genetic elements present in prokaryotic cells.

- Why is supercoiling essential to a bacterial cell? What enzyme facilitates this process?

6.2 Genetic Elements: Chromosomes and Plasmids

Structures containing genetic material (DNA in cells but RNA in some viruses) are called *genetic elements*, and the main genetic element in prokaryotic cells is the **chromosome**. However, other genetic elements play important roles in microbes and these include

Figure 6.6 Coupled transcription and translation in prokaryotic cells.

(a) Fluorescence microscopy and protein tagging of actively growing *Escherichia coli* cells illustrating the position of RNA polymerases and ribosomes performing transcription and translation, respectively. The combined photo (bottom image) shows that transcription and translation are occurring concurrently in the cell. (b) Location of the nucleoid, RNA polymerases, mRNA, and ribosomes in the cell during coupled transcription and translation. (c) Schematic illustration in a single cell of a ribosome actively translating an mRNA as it is being synthesized by RNA polymerase.

virus genomes (discussed in Chapters 5 and 11), *plasmids*, *organellar genomes*, and *transposable elements* (Table 6.1). Most *Bacteria* and *Archaea* contain a single circular chromosome containing all (or most) of the organism's genes. Although a single chromosome is the rule in prokaryotic cells, there are exceptions, as a few contain two or even three chromosomes. Eukaryotic genomes, by contrast, are composed of two or more chromosomes containing linear DNA. The genomes of viruses consist of *either* DNA or RNA and can be single- or double-stranded and either linear or circular.

Plasmids are circular or linear double-stranded DNA molecules that replicate separately from the chromosome and are typically much smaller than chromosomes. **Transposable elements** are sequences of DNA that are inserted into other DNA molecules but can move from one site on the DNA molecule to another, either within the same molecule or on a different DNA molecule. Chromosomes, plasmids, virus genomes, and any other type of DNA molecule may host a transposable element. Transposable elements are found in both prokaryotic and eukaryotic cells and play important roles in genetic variation (► Section 9.11).

Chromosomal Gene Arrangements

Thousands of genomes from species of *Bacteria* and *Archaea* have been completely sequenced, thus revealing the number and location (the genetic map) of the genes they possess. The genetic map of the 4,639,675-bp (4.639 Mb) chromosome of a widely studied strain of *Escherichia coli* is presented in Figure 6.7, with only a few of the organism's several thousand genes depicted. Analysis of the *E. coli* genome has revealed 4288 possible protein-encoding genes that account for 88% of the *E. coli* genome. Approximately 1% of the genome encodes tRNAs and rRNAs, and the remaining genes include regulatory sequences that may or may not be transcribed (but are not translated) and sequences that have other functions. The compact genomes of *Bacteria* and *Archaea* stand in contrast to the genomes of eukaryotes, which typically contain much more DNA than is needed to encode all the proteins required for cell function. This "extra" DNA in eukaryotes is present as intervening DNA between coding sequences (the intervening sequences are removed before translation) or as repetitive sequences, some of which are repeated hundreds or thousands of times (Chapter 10).

Genetic mapping of the genes encoding the enzymes that function in steps of the same biochemical pathway in *E. coli* has shown that these genes are sometimes clustered. On the genetic map in Figure 6.7, a few such clusters are shown (for example, the *gal*, *trp*, and *his* clusters); each of these groups is called an *operon*, which we will discuss in Section 6.5. In contrast to these, the genes for many other

TABLE 6.1 Kinds of genetic elements

Organism	Element	Type of nucleic acid	Description
Virus	Virus genome	Single- or double-stranded DNA or RNA	Relatively short, circular or linear
<i>Bacteria</i> , <i>Archaea</i>	Chromosome	Double-stranded DNA	Extremely long, usually circular
<i>Eukarya</i>	Chromosome	Double-stranded DNA	Extremely long, linear
Mitochondrion or chloroplast	Organellar genome	Double-stranded DNA	Medium length, usually circular
All organisms	Plasmid ^a	Double-stranded DNA	Relatively short circular or linear, extrachromosomal
All organisms	Transposable element	Double-stranded DNA	Always found inserted into another DNA molecule

^aPlasmids are uncommon in eukaryotes.

Figure 6.7 The chromosome of *Escherichia coli* strain K-12. Map distances are given in 100 kilobases of DNA. The chromosome contains 4,639,675 base pairs and 4288 open reading frames (genes). Depending on the DNA strand, the locations of a few genes and operons are indicated. Replication (Figure 6.5 and see Figures 6.15 and 6.16) proceeds in both directions from the origin of DNA replication, *oriC*, indicated in red.

biochemical pathways in *E. coli* are not clustered. For example, genes for maltose degradation (*mal* genes, Figure 6.7) are scattered throughout the chromosome. In fact, analysis of the *E. coli* chromosome has shown that over 70% of the predicted or known transcriptional units are of only a single gene and that only 6% of operons have four or more genes. Thus operons, as efficient an arrangement of genes as they may be, appear to be the exception rather than the rule.

Plasmids

Many *Bacteria* and *Archaea* contain plasmids in addition to their chromosome(s). Most plasmids are nonessential since with rare exception they do not contain genes required for growth under all conditions. Thousands of different plasmids are known, and over 300 different plasmids have been isolated from strains of *E. coli* alone. Virtually all plasmids consist of double-stranded DNA and exist in the cytoplasm as free DNA. Most plasmids are circular, but many are linear and vary in size from approximately 1 kbp to more than 1 Mbp.

Typical plasmids are less than 5% of the size of the chromosome (Figure 6.8), and some bacteria contain several different plasmids. Moreover, different plasmids may be present in different *copy number*. For example, some plasmids may be present in only one or a few copies per cell, whereas others may be present in over 100 copies. Enzymes that replicate chromosomal DNA also replicate plasmids. Some of the genes encoded on a plasmid function to direct the initiation of plasmid replication and to partition replicated plasmids between daughter cells.

Although by definition plasmids do not encode functions essential to the host, plasmids may carry genes that profoundly influence host cell physiology; for example, plasmid genes may encode enzymes for some special metabolism that ensures survival under certain conditions. Among the most widespread and well-studied groups of plasmids are the resistance plasmids, called *R plasmids*, which confer resistance to antibiotics or other growth inhibitors. The resistance genes encode proteins that either inactivate the antibiotic or protect

Figure 6.8 The bacterial chromosome and bacterial plasmids, as seen in the electron microscope. The plasmids (arrows) are the circular structures and are much smaller than the main chromosomal DNA. The cell (large, tan structure) was broken gently so the DNA would remain intact.

the cell in some other way (► Section 8.11), and several antibiotic resistance genes can be encoded on a single R plasmid. Plasmid R100 (Figure 6.9), for example, encodes resistance to sulfonamides, streptomycin, spectinomycin, fusidic acid, chloramphenicol, and tetracycline,

Figure 6.9 Genetic map of the resistance plasmid R100. The inner circle shows the size in kilobase pairs. The outer circle shows the location of major antibiotic resistance genes and other key functions: *mer*, mercuric ion resistance; *sul*, sulfonamide resistance; *str*, streptomycin resistance; *cat*, chloramphenicol resistance; *tet*, tetracycline resistance; *oriT*, origin of conjugative transfer; *tra*, transfer functions. The locations of insertion sequences (IS) and the transposon Tn10 are also shown. Genes for plasmid replication are found in the region from 88 to 92 kbp.

as well as the toxic heavy metal mercury. Pathogenic bacteria resistant to antibiotics are of considerable medical significance, and their increasing incidence is correlated with the increasing use of antibiotics for treating infectious diseases in humans and animals (Chapter 28).

Pathogenic bacteria express a variety of plasmid-encoded *virulence factors* that assist them in establishing infections. For example, the ability of a pathogen to attach to and colonize specific host tissues and to produce toxins, enzymes, and other invasive molecules that damage the host are sometimes plasmid encoded. Some bacteria also produce proteins called **bacteriocins** that inhibit or kill closely related species of bacteria (or even different strains of the same species of bacteria), and the genes encoding these bacteriocins and other proteins that protect the producing organism are typically found on plasmids.

In a few cases plasmids encode properties that are fundamental to the ecology of the bacterium. For example, the ability of the soil bacterium *Rhizobium* to form nitrogen-fixing nodules on the roots of plants (► Section 23.4) requires certain functions encoded by plasmids. Other plasmids confer special metabolic properties. For example, the ability to degrade hydrocarbons or toxic pollutants, such as polychlorinated biphenyls (PCBs) and herbicides or other pesticides, is often plasmid encoded. In addition, plasmids play a crucial role in the horizontal gene transfer process called conjugation that we consider in detail later (Chapter 9).

- What are viruses and plasmids?
- What properties does an R plasmid confer on its host cell?

II • Copying the Genetic Blueprint: DNA Replication

DNA replication must occur in a cell before it can divide. This process has a unique dimension in prokaryotic cells because their circular chromosome allows bidirectional DNA synthesis.

DNA replication is necessary for cells to divide, whether to reproduce new organisms, as in unicellular microorganisms, or to produce new cells as part of a multicellular organism. To successfully transmit genetic information from a mother cell to an identical daughter cell, DNA replication must be extremely accurate. We review the basic principles of DNA replication here as a prelude to focusing on the process as it occurs in prokaryotic cells.

6.3 Templates, Enzymes, and the Replication Fork

DNA exists in cells as a double helix of two complementary strands (Figures 6.2 and 6.5), and if the helix is opened up, a new strand can be synthesized as the complement of each parental strand. As shown in **Figure 6.10a**, replication is thus a *semiconservative* process; in **semiconservative replication**, the two resulting double helices

each consist of one new strand and one parental strand. The DNA strand that is used to make a complementary daughter strand is called the *template strand*, and in DNA replication, each parental strand is a template for one newly synthesized strand (Figure 6.10a). The precursor of each new nucleotide in the DNA strand is a deoxynucleoside 5'-triphosphate. During insertion of this molecule, the two terminal phosphates are removed and the remaining phosphate is bonded to a deoxyribose of the growing chain (Figure 6.10b). This addition of the incoming nucleotide requires the presence of a free hydroxyl group, which is available only at the 3' end of the molecule. This leads to the important principle that DNA replication always proceeds *from the 5' end to the 3' end*, the 5'-phosphate of the incoming nucleotide being attached to the 3'-hydroxyl of the previously added nucleotide (Figure 6.10b).

Replication Enzymes

Enzymes that catalyze the polymerization of deoxynucleotides are called **DNA polymerases** (abbreviated DNA Pol), and there are five different enzymes in *Escherichia coli*, DNA Pol I–V. DNA Pol III is the primary enzyme for replicating chromosomal DNA, although DNA Pol I also plays a lesser role. The other DNA polymerases function to repair damaged DNA (► Section 9.4). DNA Pol enzymes are just some of the many enzymes that are required for DNA replication (**Table 6.2**).

TABLE 6.2 Major enzymes that participate in DNA replication in *Bacteria*

Enzyme	Encoding genes	Function
DNA gyrase	<i>gyrAB</i>	Replaces supercoils ahead of replisome
Origin-binding protein	<i>dnaA</i>	Binds origin of replication to open double helix
Helicase loader	<i>dnaC</i>	Loads helicase at origin
Helicase	<i>dnaB</i>	Unwinds double helix at replication fork
Single-strand binding protein	<i>ssb</i>	Prevents single strands from annealing
Primase	<i>dnaG</i>	Primes new strands of DNA
DNA polymerase III		Main polymerizing enzyme
Sliding clamp	<i>dnaN</i>	Holds Pol III on DNA
Clamp loader	<i>holA–E</i>	Loads Pol III onto sliding clamp
Dimerization subunit (Tau)	<i>dnaX</i>	Holds together the two core enzymes for the leading and lagging strands
Polymerase subunit	<i>dnaE</i>	Strand elongation
Proofreading subunit	<i>dnaQ</i>	Proofreading
DNA polymerase I	<i>polA</i>	Excises RNA primer and fills in gaps
DNA ligase	<i>ligA, ligB</i>	Seals nicks in DNA
Tus protein	<i>tus</i>	Binds terminus and blocks progress of the replication fork
Topoisomerase IV	<i>parCE</i>	Unlinking of interlocked circles

Figure 6.10 Overview of DNA replication. (a) In cells, DNA replication is a semiconservative process. Note that the new double helices each contain one new daughter strand (shown in red) and one parental strand. (b) Extension of a DNA chain by adding a deoxyribonucleoside triphosphate at the 3' end. Growth proceeds from the 5'-phosphate to the 3'-hydroxyl end. DNA polymerase catalyzes the reaction. The four precursors are deoxythymidine triphosphate (dTTP), deoxyadenosine triphosphate (dATP), deoxyguanosine triphosphate (dGTP), and deoxycytidine triphosphate (dCTP). Upon nucleotide insertion, the two terminal phosphates of the triphosphate are split off as pyrophosphate (PP_i). Thus, two energy-rich phosphate bonds are consumed when adding each nucleotide.

All DNA polymerases synthesize DNA in the 5' → 3' direction, but none of them can initiate a new chain *de novo*; they can only add a nucleotide onto a preexisting 3'-OH group. Thus, in order to start a new DNA chain, a **primer**, a nucleic acid molecule to which DNA polymerase can attach the first nucleotide, is required, and this primer is a short stretch of RNA rather than DNA (Figure 6.11). When the DNA helix is first opened, the enzyme **primase** makes this RNA primer, synthesizing a short stretch (11–12 nucleotides) of RNA complementary in base pairing to the template-strand DNA. At the growing end of this RNA primer is a 3'-OH group to which DNA polymerase adds the first deoxyribonucleotide. Continued extension of the molecule thus occurs as DNA rather than RNA (Figure 6.11), and the primer is eventually removed and replaced with DNA (as described shortly).

Figure 6.11 The RNA primer. Structure of the RNA–DNA hybrid formed during initiation of DNA synthesis. Orange depicts the RNA primer.

Initiation of DNA Synthesis

Before replication can begin, the double helix must be unwound to expose the template strands at the so-called **replication fork**. The enzyme **DNA helicase** unwinds the double helix (using energy from ATP) and exposes a short single-stranded region (Figure 6.12). Helicase moves along the DNA and separates the strands just in advance of the replication fork. The single-stranded region is immediately covered with copies of single-strand binding protein to stabilize the single-stranded DNA and prevent the double helix from re-forming. DNA synthesis begins at a single site on the chromosome, the *origin of replication* (*oriC*), where the protein DnaA (Table 6.2) binds and opens up the double helix. Next to assemble is helicase (DnaB), which is helped onto the DNA by a loader protein (DnaC) (Figure 6.12b). Finally, primase and DNA polymerase enzymes are loaded onto the DNA behind the helicase and initiation of DNA replication begins. As replication proceeds, the replication fork appears to move along the DNA (Figure 6.12a).

Leading and Lagging Strands and the Replication Process

Figure 6.13 depicts DNA replication at the replication fork. Recall that replication always proceeds from 5' to 3' (5' → 3'), always adding a new nucleotide to the 3'-OH of the growing chain. On the strand

Figure 6.12 DNA helicase unwinding a double helix. (a) In this schematic, the helicase is seen pulling the two antiparallel strands of DNA apart beginning from the right and moving to the left. (b) A three-dimensional model of the helicase (DnaB) along with its loader protein (DnaC, yellow and orange) based on cryo-electron microscopy.

growing from the 5'-PO₄²⁻ to the 3'-OH, called the **leading strand**, DNA synthesis occurs *continuously* because there is always a free 3'-OH at the replication fork to which a new nucleotide can be added; the leading strand must therefore be primed only once. By contrast, on the opposite strand, called the **lagging strand**, DNA synthesis occurs *discontinuously* because there is no 3'-OH at the replication fork to which a new nucleotide can attach; on this strand, primase must synthesize multiple RNA primers in order to provide free 3'-OH groups for DNA Pol III (Figure 6.13). As a result, the lagging strand forms from several short DNA fragments that are combined later to yield a continuous strand of DNA.

After synthesizing the RNA primer, primase is replaced by DNA Pol III. This enzyme complex (Table 6.2) is held on the DNA by a “sliding clamp,” which encircles and slides along the single template strands of DNA. Consequently, the replication fork contains two

polymerase core enzymes and two sliding clamps, one set for each strand. After assembly on the lagging strand, the elongation activity of DNA Pol III adds deoxyribonucleotides sequentially until it reaches previously synthesized DNA (Figure 6.14); at this point, activity of DNA Pol III stops.

To complete DNA synthesis, DNA Pol I catalyzes two different reactions. Besides synthesizing DNA, Pol I has a 5' → 3' exonuclease activity that removes the RNA primer (Figure 6.14). When the primer has been excised and replaced with DNA, Pol I is released. The *very last* phosphodiester bond in replicating DNA is made by **DNA ligase**. This enzyme seals nicks in DNAs that have an adjacent 5'-PO₄²⁻ and 3'-OH (something that DNA Pol I and Pol III are unable to do), and along with DNA Pol I, it also participates in DNA repair. DNA ligase is also important for sealing genetically manipulated DNA during molecular cloning (► Section 12.2).

We now put DNA synthesis in the context of *Archaea* and *Bacteria* to see how replication events occur around the covalently closed and circular chromosomes typical of these organisms.

Figure 6.13 Events at the DNA replication fork on the nucleoid. Note the polarity and antiparallel nature of the DNA strands. Helicase unwinds the DNA while primase adds the RNA primer. For the steps in introducing and removing supercoils from DNA, see Figure 6.4. Further events in DNA synthesis including sealing replicated fragments are shown in Figure 6.14.

Check Your Understanding

- To which end (5' or 3') of a newly synthesized strand of DNA does DNA polymerase add a nucleotide?
- In DNA replication, what is the primer composed of and why are there leading and lagging strands?
- What are the functions of DNA Pol I and III, DNA helicase, and DNA ligase?

6.4 Bidirectional Replication, the Replisome, and Proofreading

The circular nature of the bacterial and archaeal chromosome accelerates the genomic replication process. In *Escherichia coli*—and probably in all cells with circular chromosomes—DNA replication occurs *bidirectionally* from the origin of replication. There are thus *two* replication forks on each chromosome, each moving in opposite

Figure 6.14 Sealing two fragments on the lagging strand. Unlike the leading strand, where synthesis occurs in a continuous fashion, on the lagging strand, DNA fragments need to be sealed to form the intact DNA strand. (a) DNA polymerase III is synthesizing DNA in the 5′ → 3′ direction toward the RNA primer of a previously synthesized fragment on the lagging strand. (b) On reaching the fragment, DNA polymerase III leaves and is replaced by DNA polymerase I. (c) DNA polymerase I continues synthesizing DNA while removing the RNA primer from the previous fragment, and DNA ligase replaces DNA polymerase I after the primer has been removed. (d) DNA ligase seals the two fragments together. (e) The final product, complementary and antiparallel double-stranded DNA.

directions. In circular DNA, bidirectional replication leads to the formation in the replicating molecules of characteristic shapes (so-called “theta structures”) as synthesis proceeds in both a leading and a lagging fashion on each template strand (**Figure 6.15**). In an actively growing cell of *E. coli*, DNA Pol III adds nucleotides at the rate of about 1000 per second; hence, replication of the entire chromosome takes about 40 min.

The Replisome

Figure 6.13 shows the enzymes that participate in replication, and from such a schematic it may appear that the enzymes are working independently. However, this is not the case. Instead, replication proteins aggregate to form a large replication complex called the **replisome** (**Figure 6.16**). The lagging strand of DNA actually loops out to allow the replisome to move smoothly along both strands, the complex literally pulling the DNA template through it as replication proceeds. In addition to the replisome, helicase and primase form their own subcomplex within the replisome called the *primosome*. This close association facilitates the sequential activities of these two enzymes during the replication process (Figure 6.16). Table 6.2 summarizes the functions of proteins essential for DNA replication in *Bacteria*.

Figure 6.15 Replication of circular DNA: the theta structure. In circular DNA, bidirectional replication from an origin forms an intermediate structure resembling the Greek letter theta (θ). The blowup shows dual replication forks in the circular chromosome. In *Escherichia coli*, the origin of replication is recognized by the DnaA protein and the terminus of replication is recognized by the Tus protein. Note that DNA synthesis is occurring in both a leading and a lagging manner on each of the new daughter strands until the replication forks hit the terminus. Compare this figure with the illustration of the replisome in Figure 6.16.

Figure 6.16 The replisome. The replisome consists of two copies of DNA polymerase III and DNA gyrase, plus helicase and primase (together forming the primosome), and many copies of single-strand DNA-binding protein. The Tau subunits hold the two DNA polymerase assemblies and helicase together. Just upstream of the rest of the replisome, DNA gyrase removes supercoils in the DNA to be replicated. Note that the two polymerases are replicating the two individual strands of DNA in opposite directions. Consequently, the lagging-strand template loops around so that the whole replisome moves in the same direction along the chromosome.

Eventually the activity of the replisome is finished, and this is signaled when the replication forks collide at the *terminus of replication*, a site located on the opposite side of the chromosome from the origin. In the terminus region are several DNA sequences called *Ter* sites that are recognized by a protein called Tus, whose function is to block progress of the replication forks. When replication of the circular chromosome is complete, the two circular molecules are linked together, much like the links of a chain. After replication, the DNA is partitioned so that each daughter cell receives a copy of the chromosome; DNA partitioning is facilitated by FtsZ, a protein that orchestrates several key events in the cell division process (Chapter 8).

Fidelity of DNA Replication: Proofreading

DNA replication occurs with a remarkably low error rate. Nevertheless, when errors do occur, a mechanism exists to detect and correct them. Errors in DNA replication introduce *mutations*, changes in DNA sequence. Mutation rates in cells are extremely low, between 10^{-8} and 10^{-11} errors per base pair inserted. This accuracy is achieved because DNA polymerases get *two* chances to incorporate the correct base at any given site. The first chance comes when DNA Pol III inserts bases according to the base-pairing rules (Figure 6.1c). The second chance comes when a process called *proofreading* takes place (Figure 6.17).

During replication, if an incorrect base has been inserted, a mismatch in base pairing (Figure 6.1c) occurs. Both DNA Pol I and Pol III possess a $3' \rightarrow 5'$ exonuclease activity that can remove such mismatched nucleotides. The polymerase detects the error because incorrect base pairing causes a slight distortion in the topology of the double helix. After the removal of a mismatched nucleotide, the polymerase then gets a second chance to insert the correct nucleotide (Figure 6.17; part *b* shows the polymerase working in “proofread mode”). With the extremely low error rate of DNA polymerases, the chance of inserting the wrong base at the same site twice is vanishingly small. Exonuclease proofreading occurs in *Bacteria* and *Archaea*, eukaryotes, and viral DNA replication systems.

We now move on from replicating genes to consider *gene expression* as a prelude to examining synthesis of the proteins encoded by the transcribed genes.

Check Your Understanding

- What is the replisome and what are its components?
- How are the activities of the replisome stopped?
- How are errors in DNA replication kept extremely low?

Figure 6.17 Proofreading by the 3' → 5' exonuclease activity of DNA polymerase III. (a) A mismatch in base pairing at the terminal base pair leads to a distortion in DNA topology that causes the polymerase to pause briefly. This signals the proofreading activity to cut out the mismatched nucleotide, after which the correct base is inserted by the polymerase activity. (b) Cryo-electron micrograph of *Escherichia coli* DNA polymerase III bound to DNA (green strands) in proofreading mode. III • RNA Synthesis: Transcription

Transcription transforms the genetic information inscribed in DNA into RNA, a form of nucleic acid that the cell's protein-synthesizing machinery can recognize and process into the many different types of proteins that a given cell needs.

Transcription—RNA synthesis off of a DNA template—yields three main forms of RNA: *messenger* (mRNA), *transfer* (tRNA), and *ribosomal* (rRNA) (Section 6.1). Several other minor classes of RNA exist, but most of these function in regulation (Chapter 7). RNA is both a genetic and a functional molecule. At the genetic level, mRNA encodes genetic information from the genome for the synthesis of proteins and carries this information to the ribosome. In contrast, rRNAs play both a structural and a functional role in ribosomes, while tRNAs function as the carriers of amino acids to the ribosome for protein synthesis.

There are two key differences in the chemistry of RNA and DNA: (1) RNA contains ribose instead of deoxyribose; and (2) RNA contains uracil instead of thymine. The change from deoxyribose to ribose dramatically affects the chemistry of a nucleic acid, and enzymes that act on DNA typically have no effect on RNA, and vice versa. However, the change from thymine to uracil does not affect base pairing, as these two bases pair with adenine equally well.

With the exception of a few viruses that contain double-stranded RNA genomes (Chapter 11), RNA is a single-stranded molecule. However, the primary structure (sequence of nucleotides) of some RNAs allows them to fold and exploit complementary base pairing. The term **secondary structure** refers to this folding, and the functional role an RNA plays in the cell may depend critically on its secondary structure. For example, messenger RNAs, which are typically unfolded, exist in *Bacteria* (and *Archaea*) for only a few minutes before enzymes called *ribonucleases* degrade them. By contrast, rRNAs and tRNAs (referred to as *stable RNAs*) are long-lived because their secondary structures prevent ribonuclease attack. The rapid

turnover of mRNAs in *Bacteria* and *Archaea* allows them to quickly adapt to changing environmental conditions and halt the translation of mRNAs whose products are no longer needed.

We begin with transcription in *Bacteria* and contrast this in the following section with transcriptional events in *Archaea* and *Eukarya*.

6.5 Transcription in *Bacteria*

Transcription is catalyzed by the enzyme **RNA polymerase**. Like DNA polymerase, RNA polymerase forms phosphodiester bonds but between the *ribonucleotides* rather than *deoxyribonucleotides* (Figure 6.1b). Polymerization is driven by energy released from the hydrolysis of two energy-rich phosphate bonds of the incoming ribonucleoside triphosphates. The mechanism of RNA synthesis is thus quite similar to that of DNA synthesis (Figure 6.10b): During elongation of an RNA chain, ribonucleoside triphosphates are added to the 3'-OH of the ribose of the preceding nucleotide. Thus chain growth is 5' → 3' just as in DNA synthesis, and the newly synthesized strand of RNA runs antiparallel to the DNA template strand it was transcribed from. A summary of bacterial transcription is illustrated in **Figure 6.18**.

RNA polymerase uses DNA as a template, but for any given gene, only one of the two strands is transcribed. Unlike DNA polymerase, RNA polymerase can initiate new RNA on its own; no priming is necessary as it is for DNA synthesis (Figure 6.11). Transcription continues until specific sequences called *transcription terminators* are reached, but unlike DNA replication, which copies the entire genome, transcription occurs on much smaller units of DNA, often as little as a single gene. This system allows the cell to transcribe different genes at different frequencies, depending on the needs of the cell for different proteins. Said a different way, gene expression is a *highly regulated* process. Transcriptional regulation can occur in bacterial and archaeal cells in many different ways, but the different mechanisms have a common outcome: Cell resources are conserved and cell fitness enhanced (Chapter 7).

Mastering
Microbiology
Art Activity:
Figure 6.18a
Transcription

Figure 6.18 Transcription. (a) Steps in RNA synthesis. The initiation site (promoter) and termination site are specific nucleotide sequences on the DNA. Sigma binds to the promoter region and then RNA core polymerase binds to begin transcription. RNA polymerase moves down the DNA chain, temporarily opening the double helix (creating a transcription bubble) and transcribing one of the DNA strands. (b) Electron micrograph illustrates transcription by multiple polymerases along a gene on the *Escherichia coli* chromosome. Transcription is proceeding from left to right, with the shorter transcripts on the left becoming longer as transcription proceeds.

RNA Polymerases and the Promoter Sequence

The RNA polymerase from *Bacteria*, which has the simplest structure and about which most is known, consists of five different subunits, designated β , β' , α , ω (omega), and σ (sigma), with α present in two copies (Figure 6.19). The subunits form an enzyme complex called the *RNA polymerase holoenzyme*. Sigma is not as tightly bound as the other subunits and easily dissociates to yield the *RNA polymerase core enzyme*, $\alpha_2\beta\beta'\omega$. The core enzyme alone synthesizes RNA, and sigma functions only to recognize the appropriate site on the DNA to initiate transcription (sigma dissociates from the holoenzyme once a short sequence of RNA has been formed; Figure 6.18).

To begin transcription, RNA polymerase must first recognize initiation sites on the DNA; these sites are called **promoters**. In *Bacteria*, promoters are recognized by sigma (Figure 6.20). Once RNA polymerase has bound to a promoter, transcription can proceed (Figure 6.18). In this process, the DNA helix at the promoter site is opened up by RNA polymerase, and as the polymerase moves, it unwinds the DNA in short segments to expose template DNA, creating a *transcription bubble* (Figure 6.18). Thus, an enzyme with the activity of DNA helicase is not needed. Because some genes reside on one strand of DNA while other genes reside on the other strand of DNA, promoters are present on both strands; as a result, transcription occurs in *opposite directions* on the two different strands of DNA.

Sigma Factors, Consensus Sequences, and Transcriptional Termination

Promoters are specific DNA sequences; Figure 6.20b shows the sequence of several promoters from *Escherichia coli*. All of these sequences are recognized by the same *E. coli* sigma factor called σ^{70} (the superscript 70 indicates the size of this protein in kilodaltons, a measure of atomic mass). Although these sequences are not identical, sigma recognizes two highly conserved regions within the promoter. These conserved sequences are upstream of (prior to) the transcription start site. One is 10 bases upstream, the -10 region, or *Pribnow box*. Although promoter sequences differ slightly, comparison of many -10 regions gives a consensus sequence of TATAAT. The second conserved region is about 35 bases upstream of the start site and its consensus sequence is TTGACA (Figure 6.20). In *E. coli*, promoters that conform most closely to the consensus sequence are more effective in binding RNA polymerase. Such promoters are called *strong promoters* and are very useful in genetic engineering, where it is desirable to have only one or a restricted set of genes heavily transcribed in order to produce more of a particular protein product (Chapter 12).

While most genes in *E. coli* require σ^{70} for transcription, several alternative sigma factors exist that recognize different consensus sequences (Table 6.3). Each alternative sigma factor is specific for a group of genes required under special circumstances, and thus the presence or absence of a specific sigma factor is a mechanism for regulating gene expression (Chapter 7). That is, by changing the rate of either synthesis or degradation of a particular sigma factor, the cell can control the transcription of entire gene families.

Figure 6.19 RNA polymerase from the three domains. Surface representation of multi-subunit cellular RNA polymerase structures from *Bacteria* (left, *Thermus aquaticus* core enzyme), *Archaea* (center, *Sulfolobus solfataricus*), and *Eukarya* (right, *Saccharomyces cerevisiae* RNA Pol II). Orthologous subunits are depicted by the same color. A unique subunit in the *S. solfataricus* RNA polymerase is not shown in this view.

Units of Transcription and Polycistronic mRNA

Genetic information is organized into *transcriptional units*, segments of DNA that are transcribed into a single RNA molecule bounded by their initiation and termination sites. Some transcriptional units contain RNA transcribed from a single gene, whereas

others are formed from two or more genes (*cotranscribed genes*). Most genes encode proteins, but others encode nontranslated RNAs, such as ribosomal or transfer RNAs. For example, prokaryotic cells produce three size classes of rRNA: 16S, 23S, and 5S (the S refers to *Svedberg units*, a sedimentation coefficient that provides

Figure 6.20 The interaction of RNA polymerase with a bacterial promoter. (a) Cryo-electron micrograph of *Escherichia coli* RNA polymerase with sigma factor (together constituting the holoenzyme) bound to closed promoter region. Image credit: Glyde, R., Ye, F.Z., Darbari, V.C., Zhang, N., Buck, M., and Zhang, X.D. EMDatabank: EMD-3695. (b) Six different promoter sequences identified in the *E. coli* genome. The

contacts of the RNA polymerase and sigma factor with the -35 region and the Pribnow box (-10 sequence) are shown. Transcription begins at a unique base just downstream from the Pribnow box. Below the actual sequences at the -35 and Pribnow box regions are consensus sequences derived from comparing many promoters. Although the consensus sequences are not identical, they constitute a sufficiently similar pattern

recognized through contacts between the bases in the DNA and specific domains of the sigma factor. Note that although sigma recognizes the promoter sequences on the $5' \rightarrow 3'$ (dark green) strand of DNA, the RNA polymerase core enzyme will actually transcribe the light green strand (that runs $3' \rightarrow 5'$) because core enzyme synthesizes only in a $5' \rightarrow 3'$ direction (Figure 6.13).

^aSuperscript number indicates size of protein in kilodaltons. Many factors also have other names, for example, σ^{70} is also called σ^D . See Figure 6.20 for a description of how the recognition (consensus) sequence is recognized by the sigma factor.

^bN = any nucleotide.

a measure of particle size based on sedimentation rate), and their genes are cotranscribed to form a single transcriptional unit that also includes a tRNA (Figure 6.21). This transcriptional unit is subsequently “processed” by proteins that cut them to form the individual rRNAs or tRNAs.

As we have previously considered, genes that encode several enzymes of a particular metabolic pathway in prokaryotic cells, for example the biosynthesis of a particular amino acid, are often

Figure 6.21 A ribosomal rRNA transcription unit from *Bacteria* and its subsequent processing. In *Bacteria*, all rRNA transcription units have the genes in the order 16S rRNA, 23S rRNA, and 5S rRNA (shown approximately to scale). In this particular transcriptional unit, the spacer between the 16S and 23S rRNA genes contains a tRNA gene. In other transcription units this region may contain more than one tRNA gene. Often one or more tRNA genes also follow the 5S rRNA gene and are cotranscribed. *Escherichia coli* contains seven rRNA transcription units.

Figure 6.22 Operon and polycistronic mRNA structure. Note that a single promoter controls the three genes within the operon and that the polycistronic mRNA molecule contains an open reading frame (ORF) corresponding to each gene.

clustered together in an **operon** (Section 6.2). An operon is transcribed to form a single mRNA that encodes several different proteins and is regulated as a unit. Assembling genes for the same biochemical pathway or genes needed under the same conditions into an operon allows for their coordinate expression. During transcription, RNA polymerase proceeds through the operon and transcribes the entire set of genes into a single mRNA called a *polycistronic mRNA* (Figure 6.22). Polycistronic mRNAs contain multiple *open reading frames*, portions of the mRNA that actually encode amino acids (Section 6.9). When this mRNA is translated, several polypeptides are synthesized sequentially by the same ribosome. Bacterial and archaeal genomes can also possess *regulons*, which are multiple operons that encode genes whose products are needed under the same conditions. We discuss the regulation of operons and the coordinated expression of regulons in Chapter 7.

Termination of Transcription

In a growing bacterial cell, only those genes that need to be expressed are usually transcribed; therefore, it is critical that transcription end at the correct position. **Termination** of transcription is governed by specific base sequences on the DNA. In *Bacteria* a common termination signal is a GC-rich sequence containing an *inverted repeat* with a central nonrepeating segment. When such a DNA sequence is transcribed, the RNA forms a stem-loop structure by intra-strand base pairing (Figure 6.23). Coding sequences for stem-loops followed by a run of adenines in the DNA template (which yields a run of uridines in the RNA) are strong transcription terminators because a stretch of U–A base pairs are formed that hold the RNA and DNA together. However, this structure is very weak since U–A base pairs have only two hydrogen bonds rather than the three that form in G–C pairs (Figure 6.1c). Thus, RNA polymerase pauses at the stem-loop, and the DNA and RNA dissociate at the run of uridines, terminating transcription.

A second mechanism for terminating transcription is catalyzed by the terminator protein Rho. Rho does not bind to RNA polymerase or to the DNA but binds tightly to RNA and moves down the chain toward the RNA polymerase–DNA complex. Once RNA polymerase has paused at a Rho-dependent termination site (a specific nucleotide sequence on the DNA template), Rho causes both the RNA and

RNA polymerase to be released from the DNA, thus terminating transcription.

Now that we have grasped the essentials of transcription in *Bacteria*, we turn our attention to this crucial cell process in *Archaea* and *Eukarya*, where the phylogenetic connection between these two domains (◀ Section 1.15) will be apparent in their mechanisms of transcription.

6.6 Transcription in *Archaea* and *Eukarya*

Here we discuss key elements of transcription in *Archaea* and *Eukarya* that differ from those of *Bacteria*. Although in both *Archaea* and *Eukarya* the overall flow of genetic information is the same as in *Bacteria*, some details differ, and in eukaryotic cells the presence of the nucleus complicates the routing of genetic information. Many of the details of transcription (and translation) in *Archaea* resemble those in *Eukarya* more closely than *Bacteria*. However, *Archaea* also share some transcriptional similarities with *Bacteria*, such as operons. We begin our discussion at center stage with a consideration of RNA polymerase.

Archaeal and Eukaryotic RNA Polymerases, Promoters, and Terminators

Archaeal and eukaryotic RNA polymerases are similar and more complex than those of *Bacteria*. *Archaea* contain only a single RNA polymerase while eukaryotes have three. The archaeal RNA polymerase most closely resembles eukaryotic RNA polymerase II and is composed of 11–13 subunits, depending on the species (eukaryotic RNA polymerase II has 12 or more subunits). These contrast with the comparatively simple four-subunit RNA polymerase core enzyme of *Bacteria* (Figure 6.19).

We learned the importance of the promoter and its recognition sequences to the overall process of transcription in Section 6.5. The most important recognition sequence in archaeal and eukaryotic promoters is the 6- to 8-base-pair “TATA” box, located 18–27 nucleotides upstream of the transcriptional start site (Figure 6.24). The TATA box is recognized by the *TATA-binding protein* (TBP), one of the many *transcription factors* present in *Archaea* and eukaryotes. Upstream of the TATA box is the *B recognition element* (BRE) sequence that is recognized by archaeal transcription factor B (TFB). In addition, a specific initiator element sequence is located at the start of transcription. Once TBP has bound to the TATA box and TFB has bound to the BRE, then archaeal RNA polymerase can bind and initiate transcription. This process is similar in eukaryotes except that several additional transcription factors are required.

Less is known about transcription termination in *Archaea* than in *Bacteria*, although some archaeal genes have inverted repeats followed by an AT-rich sequence similar to those present in many bacterial transcription terminators (Section 6.5). One other type of suspected transcription terminator lacks inverted repeats but contains repeated runs of thymines. While no Rho-like proteins (Section 6.5)

Figure 6.24 Promoter architecture and transcription in *Archaea*. (a) Three promoter elements are critical for promoter recognition in *Archaea*: the initiator element (INIT), the TATA box, and the B recognition element (BRE). The TATA-binding protein (TBP) binds the TATA box; transcription factor B (TFB) binds to both BRE and INIT. Once both TBP and TFB are in place, RNA polymerase binds. Note that the colors of the different transcription factors match those in the molecular model shown to the right. (b) Surface representation of the archaeal pre-initiation complex (with TBP and TFB) and including transcription factor E (TFE). TFE is an optional transcription factor frequently associated with the archaeal pre-initiation complex.

have been found in either *Archaea* or *Eukarya*, a separate transcriptional termination protein has been identified in *Euryarchaeota* (a major phylum of *Archaea*) called Eta. Eta binds to DNA upstream of the transcription bubble, and when it collides with the archaeal RNA polymerase, it bumps the polymerase off of the DNA. In eukaryotes, the termination process differs depending on the RNA polymerase and often requires a specific termination factor protein.

RNA Processing in Eukaryotes and Intervening Sequences in *Archaea*

In contrast to *Bacteria*, *Eukarya* contain many genes that are split into two or more coding regions separated by noncoding regions. The coding sequences are called **exons** while the intervening noncoding regions are called **introns**. Thus, the transcripts from exons typically require alterations—known as **RNA processing**—to form **mature RNAs** suitable for translation. The term **primary transcript** refers to the RNA molecule that is originally transcribed before the introns are removed to form the mature mRNA containing only exons. The process by which introns are removed and exons are joined is called **splicing** (Figure 6.25).

RNA splicing occurs in the nucleus by the activity of a macromolecular complex containing both RNA and protein called the

spliceosome. The proteins of the spliceosome excise the intron(s) from the primary transcript and link the flanking exons to form a contiguous protein-encoding mature mRNA (Figure 6.25). While intervening sequences in genes encoding proteins are extremely rare in *Archaea*, several archaeal tRNA- and rRNA-encoding genes contain introns that must be removed after transcription to generate the mature tRNA or rRNA. In analogy to the introns of eukaryotes, these intervening sequences are called “archaeal introns”; however, their processing is catalyzed by a special ribonuclease rather than by a spliceosome-type complex.

Two other steps in the processing of mRNA in *Eukarya* are unique to this domain, and both steps take place in the nucleus prior to splicing (Figure 6.26). The first step, called **capping**, occurs before transcription is complete. Capping is the addition of a methylated guanine nucleotide at the 5′-phosphate end of the mRNA (Figure 6.26). The cap is added in reverse orientation relative to the rest of the mRNA molecule and is needed to initiate translation. The second step, **polyadenylation**, consists of trimming the 3′ end of the primary transcript and adding 100–200 adenine residues, called the **poly(A) tail** (Figure 6.26). The poly(A) tail stabilizes mRNA against nuclease attack, and following translation, it must be removed before the mRNA can be degraded.

- What specific eukaryotic enzyme does the archaeal RNA polymerase resemble?
- What steps take place in the processing of eukaryotic RNA?

Figure 6.26 Processing of the primary transcript into mature mRNA in eukaryotes.

The processing steps include adding a cap at the 5' end, removing the introns, and clipping the 3' end of the transcript while adding a poly(A) tail. All these steps are carried out in the nucleus. The location of the start and stop codons to be used during translation are indicated.

IV • Protein Synthesis: Translation

The culmination of replication and transcription is translation, the actual production of proteins by the cell's remarkable biomolecular machine, the ribosome.

Once transcription has occurred, the mRNAs are translated into protein. Translation requires many proteins and RNAs (in addition to mRNA) that combine to form a key cellular structure called the ribosome. How an mRNA and a ribosome interact to produce a cell's array of proteins is what we consider now, and we begin with a refresher section on the basic properties of proteins.

6.7 Amino Acids, Polypeptides, and Proteins

Proteins play major roles in cell function. Three major classes of cellular proteins are *catalytic proteins*, *structural proteins*, and *regulatory proteins*. *Enzymes* are the catalysts for chemical reactions that occur in cells (◀ Section 3.5). Structural proteins are parts of the major structures of the cell: membranes, the cell envelope, ribosomes, and so on (Chapter 2). Regulatory proteins control most cell processes by a variety of mechanisms, including binding to DNA and affecting transcription (Chapter 7). However, regardless of function, all proteins have certain basic features in common.

Composition

Proteins are polymers of **amino acids**, organic compounds that contain both an amino group ($-\text{NH}_2$) and a carboxylic acid group ($-\text{COOH}$) attached to the α -carbon (Figure 6.27a). Bonds between

Figure 6.27 Structure of the 22 genetically encoded amino acids. (a) General structure. (b) R group structure. The three-letter codes for the amino acids are to the left of the names, and the one-letter codes are in parentheses to the right of the names. Pyrrolysine has thus far been found only in certain methanogenic *Archaea*.

the carboxyl carbon of one amino acid and the amino nitrogen of a second (formed through the elimination of water) are known as **peptide bonds** (Figure 6.28). Two amino acids bonded by peptide linkage constitute a *dipeptide*; three amino acids, a *tripeptide*; and so on. When many amino acids are linked, they form a **polypeptide**. A protein consists of one or more polypeptides. The number of amino acids differs greatly from one protein to another, from as few as 15 to as many as 10,000 (see Figure 6.41).

Each amino acid has a unique side chain (abbreviated R) bonded to its α -carbon; it is this side chain that governs the chemical properties of the amino acid. Side chains vary considerably, from as simple

as a hydrogen atom in the amino acid glycine to aromatic rings in phenylalanine, tyrosine, and tryptophan (Figure 6.27b). Amino acids with chemically related side chains often show similar chemical properties and are thus grouped into related amino acid "families" (Figure 6.27b). For example, the side chain may contain a carboxylic acid group, as in aspartic acid or glutamic acid, rendering the amino acid *acidic*. Others contain additional amino groups, making them positively charged and *basic*. Several amino acids contain hydrophobic side chains and are grouped together as *nonpolar* amino acids. Cysteine contains a sulfhydryl group ($-\text{SH}$). Using their sulfhydryl groups, two cysteines can form a disulfide linkage ($\text{R}-\text{S}-\text{S}-\text{R}$) that connects two polypeptide chains.

Protein Diversity and Structures

The diversity of chemically distinct amino acids makes possible an enormous number of structurally unique proteins that can have widely different biochemical properties. If one assumes that an average polypeptide contains 300 amino acids, then 22^{300} different polypeptide sequences are theoretically possible. No cell has anywhere near this many different proteins. A cell of *Escherichia coli* contains around 2000 different kinds of proteins; the exact number of different kinds produced is highly dependent on the resources (nutrients) and growth conditions employed.

The linear sequence of amino acids in a polypeptide is its *primary structure*. This ultimately determines the folding pattern of the polypeptide, which in turn determines its biological activity. Even as

Figure 6.28 Peptide bond formation. R_1 and R_2 refer to the side chains of the amino acids. Note that following peptide bond formation, a free OH group is present at the C-terminus for formation of the next peptide bond.

Figure 6.29 Secondary structure of polypeptides. (a) Hydrogen bonding in protein secondary structure. R represents the side chain of the amino acid. (b) α -Helix secondary structure. (c) β -Sheet secondary structure. Note that the hydrogen bonding is between atoms in the peptide bonds and does not involve the R groups.

little as a single amino acid change in the primary structure of a protein can affect its folding and thus its activity. Once formed, a polypeptide proceeds to fold to form a more stable structure. Hydrogen bonding between the oxygen and nitrogen atoms of two peptide bonds generates the *secondary structure*, either as an α -helix (imagine a polypeptide wound around a cylinder) or as a β -sheet (a repeated “back and forth” type of folding) (Figure 6.29). A single polypeptide can contain regions, called *domains*, of α -helix and regions of β -sheet secondary structure. The type of folding and its location in the molecule are determined by the primary structure and the available opportunities for hydrogen bonding.

Interactions between the R groups of the amino acids in a polypeptide generate higher-order structures. A protein’s **tertiary structure** depends largely on hydrophobic interactions, with lesser contributions from hydrogen bonds, ionic bonds, and disulfide bonds, and generates the overall three-dimensional form of the polypeptide (Figure 6.30). Many proteins consist of two or more polypeptides and thus show **quaternary structure**. In such proteins, the quaternary structure describes the number and secondary structure of polypeptides (referred to as *subunits*) in the molecule. Quaternary structures may be stabilized by various interactions and also by disulfide bonds; if cysteines located in two different polypeptides are joined, the disulfide bond links the two subunits.

When proteins are exposed to extremes of heat or pH or to certain chemicals that affect their folding, they may undergo **denaturation**. This results in the loss of a protein’s secondary, tertiary, and quaternary structure along with its biological properties. However, because peptide bonds are usually not broken, the denatured polypeptide retains its primary structure. Depending on the severity of the denaturing conditions, the polypeptide may properly refold after the

denaturant is removed. However, if refolding is not correct, the protein is permanently inactive and is degraded by proteases to release its amino acids for new protein synthesis.

Check Your Understanding

- Draw the structure of a dipeptide containing the amino acids alanine and tyrosine and outline the peptide bond.
- Differentiate between the different classes of protein structure.
- What is denaturation and why is the process harmful to a cell?

Figure 6.30 Tertiary structure of polypeptides. (a) Insulin, a protein containing two polypeptide chains; note how the B chain contains both α -helix and β -sheet secondary structure and how disulfide linkages (S—S) help in dictating folding patterns (tertiary structure). (b) Ribonuclease, a large protein with several regions of α -helix and β -sheet secondary structure.

6.8 Transfer RNA

With a primer on proteins behind us, we now consider protein synthesis. But to do so, we must first understand the role of transfer RNA (tRNA). Transfer RNAs function to carry amino acids to the translation machinery. To ensure that they carry the correct amino acid, each tRNA contains a specific three-nucleotide sequence called the **anticodon**, the group of three bases that recognizes a codon (a three-base code for an amino acid) on the mRNA (Section 6.10). The correct amino acid (called the *cognate* amino acid) is linked to a specific tRNA by an enzyme called an **aminoacyl-tRNA synthetase**. For each amino acid, a separate aminoacyl-tRNA synthetase exists that specifically binds both the cognate amino acid and the tRNA that contains the corresponding anticodon, thus ensuring that each tRNA receives its correct amino acid. If an amino acid is encoded by more than one codon, a single aminoacyl-tRNA synthetase will recognize the anticodon on any of the tRNAs for that amino acid.

General Structure of Transfer RNA

There are about 60 different tRNAs in prokaryotic cells and 100–110 in human cells. Transfer RNAs are short (73–93 nucleotides), single-stranded molecules that contain extensive secondary structure. Certain base sequences and secondary structures are invariant for tRNAs, whereas other parts are variable. Transfer RNAs also contain some purine and pyrimidine bases that are modified from the bases found in other classes of RNA, and these modifications occur after transcription. These unusual bases include pseudouridine (Ψ), inosine, dihydrouridine (D), ribothymidine, methyl guanosine, dimethyl guanosine, and methyl inosine. The mature and active tRNA also contains extensive double-stranded regions formed by

internal base pairing when the single-stranded molecule folds back on itself (**Figure 6.31**).

A tRNA can be depicted in the shape of a cloverleaf (**Figure 6.31a**). Some regions of tRNA secondary structure are named after the modified bases found there (for example, the T Ψ C and D loops) or after their functions (for example, the anticodon loop and acceptor stem). The three-dimensional model of a tRNA shown in **Figure 6.31b** is a more realistic view of the molecule and shows how bases that appear widely separated in the cloverleaf model are actually much closer together when viewed in 3D. This close proximity allows some of the bases in one loop to pair with bases in another loop (**Figure 6.31b**).

At the 3' end (the acceptor end) of all tRNAs are three unpaired nucleotides. The sequence of these three nucleotides is always cytosine-cytosine-adenine (CCA), and they are absolutely essential for function. However, in most organisms the 3' CCA is not encoded in the tRNA gene on the chromosome; instead, each nucleotide is added sequentially by a protein called *CCA-adding enzyme*, using CTP and ATP as substrates. The cognate amino acid is then covalently attached to the terminal adenosine of the CCA end of its corresponding tRNA. From this location, the amino acid is incorporated into the growing polypeptide chain on the ribosome by a mechanism to be described in Section 6.10.

Recognition, Activation, and Charging of tRNAs

Recognition of the correct tRNA by an aminoacyl-tRNA synthetase is obviously crucial to the fidelity of translation and requires that specific contacts be made between regions of the tRNA and the synthetase (**Figure 6.32**). As might be expected because of its unique sequence, the anticodon of the tRNA is important in recognition by

Figure 6.31 Structure of a transfer RNA. (a) The conventional cloverleaf structural drawing of yeast phenylalanine tRNA. The amino acid is attached to the ribose of the terminal A at the acceptor end. A, adenine; C, cytosine; U, uracil; G, guanine; T, thymine; Ψ , pseudouracil; D, dihydrouracil; m, methyl; Y, a modified purine. (b) The tRNA molecule folds so that the D loop and T Ψ C loops are close together and associate by hydrophobic interactions.

Figure 6.32 Aminoacyl-tRNA synthetase. Mode of activity of an aminoacyl-tRNA synthetase. Recognition of the correct tRNA by a particular synthetase involves contacts between specific nucleic acid sequences in the D loop and acceptor stem of the tRNA and specific amino acids of the synthetase. In this diagram, valyl-tRNA synthetase (specific for the amino acid valine) is shown catalyzing the final step of the reaction, where the valine in valyl-AMP is transferred to tRNA. The computer model on the bottom right shows the interaction of the prolyl-tRNA synthetase from *Thermus thermophilus* with its tRNA.

the synthetase. However, other contact sites between the tRNA and the synthetase are also important, including parts of the acceptor stem and D loop of the tRNA (Figure 6.31a).

The specific reaction between amino acid and tRNA catalyzed by the aminoacyl-tRNA synthetase begins with *activation* of the amino acid by reaction with ATP:

The aminoacyl-AMP intermediate formed remains bound to the tRNA synthetase until collision with the appropriate tRNA molecule. Then, as shown in Figure 6.32, the activated amino acid is bonded to the CCA stem of its tRNA to form a *charged tRNA*:

The pyrophosphate (PP_i) formed in the first reaction is split into two molecules of inorganic phosphate. Because ATP is used and AMP is formed in these reactions, a total of *two* energy-rich phosphate bonds are expended to charge a tRNA with its cognate amino acid. After activation and charging, the aminoacyl-tRNA leaves the

synthetase. In the next step, it will be bound by a ribosome where actual polypeptide synthesis occurs.

- What is the function of the anticodon of a tRNA?
- What is the function of the acceptor stem of a tRNA?
- What steps are required to form a charged tRNA?

6.9 Translation and the Genetic Code

The heart of genetic information transfer is the correspondence between the nucleic acid template and the amino acid sequence of a polypeptide. This correspondence is rooted in the **genetic code**. An mRNA triplet of three bases, called a **codon**, encodes each specific amino acid (the codons themselves are encoded by the organism's genome). The 64 possible codons (four bases taken three at a time = 4^3) are shown in Table 6.4. Note that in addition to the codons for amino acids, there are also codons for starting and stopping translation. Here we focus on translation in *Bacteria*, with *Escherichia coli* as the model.

Properties of the Genetic Code

There are 22 naturally occurring amino acids and because there are 64 codons, several amino acids can be encoded by more than one codon. A code such as this that lacks one-to-one correspondence between “word” (that is, the amino acid) and code (codon) is called a *degenerate code*. A codon is recognized by specific base pairing with a complementary sequence on the *anticodon*, located on a tRNA (Section 6.8 and Figures 6.31 and 6.32). If this base pairing were always the standard pairing of A with U and G with C, then at least one specific tRNA would be needed to recognize each codon. In some cases, this is true. For instance, there are six different tRNAs in *Escherichia coli* for the amino acid leucine, one for each codon (Table 6.4). By contrast, some tRNAs can recognize more than one codon. For example, although there are *two* lysine codons in *E. coli*, there is only *one* lysyl tRNA, whose anticodon can base-pair with *either* AAA or AAG. In these cases, the anticodon forms standard base pairs at only the first two positions of the codon and tolerates irregular base pairing at the third position. This phenomenon is called **wobble** and is illustrated in Figure 6.33.

If an amino acid is encoded by multiple codons, the codons are typically closely related in base sequence, usually differing at only their third position (Table 6.4) to allow for wobble (Figure 6.33). Interestingly, not all multiple codons for a given amino acid are used at the same frequency, leading to a **codon bias** that varies from organism to organism. Codon bias is correlated with a corresponding bias in the concentration of different tRNA molecules. That is, a tRNA whose anticodon corresponds to a rarely used codon is typically produced at low levels.

Start and Stop Codons and Reading Frames

Messenger RNA is translated in *Bacteria* beginning with its **start codon** (AUG, Table 6.4), which encodes a chemically modified methionine called *N-formylmethionine* (although AUG at the *beginning* of a coding region encodes *N-formylmethionine*, AUG *within*

^aAUG encodes *N*-formylmethionine at the beginning of polypeptide chains of *Bacteria*.

the coding region encodes methionine). By contrast, the translational machinery in *Archaea* and *Eukarya* insert an unmodified methionine as the first amino acid in a polypeptide.

With a triplet code it is critical for translation to begin at the correct nucleotide. If it does not, the whole reading frame of the mRNA will be shifted and thus an entirely different (and likely inactive) protein will be made. Alternatively, if the shift introduces a stop codon (Table 6.4) into the reading frame, the polypeptide will terminate prematurely. The reading frame that when translated yields the polypeptide encoded by the gene is called the 0 (zero) frame; the other possible reading frames (−1 and +1) do not encode the same amino acid sequence (Figure 6.34). Reading frame fidelity is governed by interactions between mRNA and rRNA within the ribosome. In *Bacteria*, ribosomal RNA recognizes a specific AUG on the mRNA as a start codon with the aid of an upstream sequence in the mRNA called the *ribosome-binding site* (RBS) (also called the *Shine–Dalgarno*

Figure 6.33 The wobble concept. Base pairing is more flexible for the third base of the codon than for the first two. Only a portion of the tRNA is shown here.

sequence after its discoverers). This upstream alignment requirement explains why some mRNAs from *Bacteria* can use other start codons, such as GUG. However, because of the RBS, even these unusual start codons direct the incorporation of *N*-formylmethionine as the initiator amino acid (see Figure 6.36).

The codons UAA, UAG, and UGA (Table 6.4) are **stop codons**, and they signal the termination of translation of a protein-coding sequence on the mRNA. Stop codons are also called **nonsense codons**, because they interrupt the “sense” of the growing polypeptide when they terminate translation. In a few rare cases in *Bacteria* and *Archaea*, nonsense codons encode the unusual amino acids

Figure 6.34 Possible reading frames in an mRNA. An interior sequence of an mRNA is shown. (a) The amino acids that would be encoded if the ribosome is in the correct reading frame (designated the “0” frame). (b) The amino acids that would be encoded by this region of the mRNA if the ribosome were in the −1 reading frame. (c) The amino acids that would be encoded if the ribosome were in the +1 reading frame.

selenocysteine and pyrrolysine (Figure 6.27). When this occurs, specific tRNAs are employed whose anticodons read these stop codons. What controls this unusual occurrence is a recognition sequence just downstream of the now-coding stop codon that signals the incorporation of tRNAs containing selenocysteine or pyrrolysine rather than stopping translation. A few other microbes use conventional stop codons to encode amino acids, but in these cases the organisms have simply dispensed with using these particular stop codons as translational stop sites.

If an mRNA can be translated, it is because it contains an **open reading frame (ORF)**: a start codon followed by a number of codons and then a stop codon in the same reading frame as the start codon. Using computational methods, a DNA base sequence can be scanned to search for open reading frames. In addition to looking for start and stop codons, computer analyses may include a search for promoters and ribosome-binding sequences as well in order to confirm the ORF as protein encoding.

The search for ORFs is central to the field of genomics (Chapter 10), for if an unknown piece of DNA has been sequenced, the presence of an ORF implies that it can encode protein. In this way, computational analyses of sequenced microbial genomes can reveal much about the biology of an organism.

- What is codon bias?
- If you were given a nucleotide sequence, how would you find ORFs?

6.10 The Mechanism of Protein Synthesis

Protein synthesis is a dynamic process that can be broken down into three major steps: *initiation*, *elongation*, and *termination*. In addition to mRNA, tRNA, and ribosomes, translation requires a number of initiation, elongation, and termination proteins and the energy-rich compound guanosine triphosphate (GTP) to provide the energy to drive the process.

Ribosomes and the Initiation of Translation

Ribosomes are large complexes of proteins and RNAs where the cell's proteins are biosynthesized (Figure 6.35). A cell may have many thousands of ribosomes, the number increasing at higher growth rates. Each ribosome consists of two subunits. *Bacteria* and *Archaea* have 30S and 50S ribosomal subunits that yield intact 70S ribosomes. Each ribosomal subunit contains specific ribosomal RNAs (rRNAs) and ribosomal proteins. The 30S subunit contains 16S rRNA and 21 proteins, and the 50S subunit contains 5S and 23S rRNA and 31 proteins. Thus, in *Escherichia coli*, there are 52 distinct ribosomal proteins, most present at one copy per ribosome. The ribosome is a highly dynamic structure, and its subunits alternately associate and dissociate during the translational process (see Figures 6.36 and 6.37) while interacting with many other proteins. In addition, several cytoplasmic proteins called *translation factors* are essential for translation and interact with the ribosome at various stages of the translational process.

Figure 6.35 Ribosome structure. Crystal structure of the *Thermus thermophilus* 70S ribosome. 50S and 30S subunits are indicated. Each subunit is composed of several distinct proteins; the 50S subunit contains 23S and 5S rRNAs, and the small subunit contains 16S rRNA.

In *Bacteria*, initiation of protein synthesis begins with a free 30S ribosomal subunit (Figure 6.36). From this, an *initiation complex* forms consisting of the 30S subunit, mRNA, formylmethionine tRNA (the initiator tRNA in *Bacteria*; after polypeptide completion, the formyl group is removed), and the initiation factors IF1, IF2, and IF3. GTP is also required for this step. Next, a 50S ribosomal subunit is added to the initiation complex to form the active 70S ribosome (Figures 6.35 and 6.36). Just preceding the start codon on the mRNA is a sequence of three to nine nucleotides that compose the ribosome-binding site (Figure 6.36). This site is toward the 5' end of the mRNA and is complementary to base sequences in the 3' end of the 16S rRNA, which is part of the ribosome. Base pairing between these two RNAs holds the ribosome–mRNA complex securely together in the correct reading frame. Polycistronic mRNA (Section 6.5) contains several RBS sequences, one upstream of each coding sequence. This allows bacterial ribosomes to translate several genes on the same mRNA because the ribosome can locate each initiation site within a message by binding to its RBS.

Elongation, Translocation, and Termination

During translation, the mRNA threads through the ribosome as its nucleotides bind to the 30S subunit. The ribosome contains other sites where the tRNAs interact. Two of these sites are located primarily on the 50S subunit and are termed the *A (acceptor) site* and the *P (peptide) site* (Figure 6.37). The A site is where the incoming charged tRNA first attaches, and the loading of a tRNA into the A site is assisted by the elongation factor EF-Tu. The P site is where the growing polypeptide chain is attached to the prior tRNA. During peptide bond formation, the growing polypeptide chain moves to the tRNA at the A site as a new peptide bond is formed. In addition to EF-Tu, elongation factor EF-Ts, as well as more GTP, is required (Figure 6.37).

Figure 6.36 The ribosome and initiation of protein synthesis. The mRNA and initiator tRNA, carrying *N*-formylmethionine (“Met”), bind first to the small subunit of the ribosome. Initiation factors (not shown) use energy from GTP to promote the addition of the large ribosomal subunit. The initiator tRNA starts out in the P site (labeled in the structure on the right-hand side of the arrow).

Figure 6.37 Elongation cycle of translation. 1. Elongation factors (not shown) use GTP to install the incoming tRNA into the A site. 2. Peptide bond formation is then catalyzed by the 23S rRNA. 3. Translocation of the ribosome along the mRNA from one codon to the next requires hydrolysis of another GTP and results in movement of the tRNA with the growing peptide to the P site. The outgoing tRNA is released from the E site. 4. The next charged tRNA binds to the A site and the cycle repeats. The genetic code, expressed as codons of mRNA, is shown in Table 6.4. Translation of a given polypeptide ends when the ribosome reaches any one of three stop codons (Table 6.4) because no tRNA has an anticodon sequence (Figure 6.33) complementary to the three-base sequence in a stop codon.

Figure 6.38 Polysomes. Translation by several ribosomes on a single messenger RNA forms the polysome. Note how the ribosomes nearest the 5' end of the message are at an earlier stage in the translation process than ribosomes nearer the 3' end, and thus only a relatively short portion of the final polypeptide has been made.

Following elongation, the tRNA holding the polypeptide is translocated from the A site to the P site, thus opening the A site for a new charged tRNA; this requires elongation factor EF-G and one molecule of GTP for each translocation event (Figure 6.37). In each translocation, the ribosome advances three nucleotides (one codon) along the mRNA, exposing a new codon at the A site. Translocation pushes the now amino acid-free tRNA to a third site, called the E (exit) site, and it is from here that the tRNA is released from the ribosome. The precision of the translocation step is critical to the accuracy of protein synthesis. That is, the ribosome must move *exactly one codon* at each step or the reading frame will change and the fidelity of translation will be compromised (Section 6.9).

Several ribosomes can translate a single mRNA molecule simultaneously, forming a complex called a *polysome* (Figure 6.38). Polysomes increase both the speed and efficiency of translation because each ribosome in the polysome makes a complete polypeptide. Note in Figure 6.38 how ribosomes in the polysome that are closest to the 5' end (the beginning) of the mRNA molecule have short polypeptides attached to them because only a few codons have been read, while ribosomes closest to the 3' end of the mRNA have nearly finished polypeptides.

Translation terminates when the ribosome reaches a stop codon (Table 6.4) because no tRNA binds to a stop codon. Instead, proteins called *release factors* (RFs) recognize the stop codon and cleave the attached polypeptide from the final tRNA, releasing the finished product. Following this, the ribosomal subunits dissociate, and the 30S and 50S subunits are then free to form new initiation complexes (Figure 6.36) and repeat the process.

Role of Ribosomal RNA in Protein Synthesis

Ribosomal RNA plays major roles in all stages of translation, from initiation to termination. By contrast, the primary role of the proteins in the ribosome is to form a scaffold to position key sequences in the ribosomal RNAs (Figure 6.35). In *Bacteria*, 16S rRNA facilitates initiation by base pairing with the ribosome-binding site on the mRNA, and, along with ribosomal proteins, it holds the mRNA in position on either side of the A and P sites. Ribosomal RNA also plays a role in ribosome subunit association, as well as in positioning tRNAs on the ribosome (Figures 6.36 and 6.37). Although charged tRNAs recognize the correct codon by codon-anticodon

base pairing (Figure 6.33), they are also bound to the ribosome by interactions between the anticodon stem-loop of the tRNA and specific sequences in the 16S rRNA. Moreover, the acceptor end of the tRNA (Figures 6.36 and 6.37) base-pairs with sequences in 23S rRNA.

In addition to roles in mRNA alignment and translocation along the transcript, ribosomal RNA also catalyzes the actual formation of peptide bonds. The peptidyl transferase reaction (formation of peptide bonds, Figure 6.28) occurs on

the 50S subunit of the ribosome and is catalyzed solely by 23S rRNA. This rRNA also plays a role in translocation and interacts with the elongation factors. Thus, in addition to its role as the structural backbone of the ribosome, ribosomal RNA plays a major catalytic role in the translation process.

Freeing Trapped Ribosomes and *Trans*-Translation

A defective mRNA that lacks a stop codon cannot be properly translated. Such a defect may arise, for example, from a mutation that removed the stop codon, from defective synthesis of the mRNA, or when partial degradation of an mRNA occurs before it is translated. If a ribosome reaches the end of an mRNA molecule and there is no stop codon, release factor cannot bind and the ribosome cannot be released from the mRNA; the ribosome is effectively “trapped.”

To deal with this problem, bacterial cells initiate a process called *trans-translation*. This process produces a small RNA molecule called *tmRNA* that frees stalled ribosomes (Figure 6.39). The “tm” in its

Figure 6.39 Freeing of a stalled ribosome by tmRNA. A defective mRNA lacking a stop codon stalls a ribosome that has a partly synthesized polypeptide attached to a tRNA (blue) in the P site. Binding of tmRNA (yellow) in the A site allows translation to continue up to the stop codon provided by the tmRNA.

name refers to the fact that tmRNA mimics both tRNA, in that it carries an amino acid (alanine), and mRNA, in that it contains a short stretch of RNA that can be translated. When tmRNA collides with a stalled ribosome, it binds alongside the defective mRNA. Protein synthesis can then proceed, first by adding the alanine on the tmRNA and then by translating the short tmRNA message. The tmRNA contains a stop codon that allows release factor to bind and disassemble the ribosome. The protein made as a result of this rescue operation is defective and is subsequently degraded. This is accomplished by a short sequence of amino acids encoded by tmRNA and added to the end of the defective protein; the sequence is a signal for a specific protease to degrade the protein. Thus, through the activity of *trans*-translation, stalled ribosomes are not inactivated but instead are freed up to participate in protein synthesis once again.

We complete this chapter by considering what happens to proteins *after* they are made but *before* they become functional. For some proteins the answer is “nothing,” but for others, functionality depends on additional activities, and we survey these now.

Check Your Understanding

- What are the components of a ribosome? What functional roles does rRNA play in protein synthesis?
- How is a completed polypeptide chain released from the ribosome?
- How does tmRNA free stalled ribosomes?

V • Protein Processing, Secretion, and Targeting

Not all proteins that exit the ribosome are “ready to go,” as some need additional folding or other processing and others need to be forwarded to specific cellular locations—such as the cytoplasmic membrane—if they are to carry out their functions properly.

While translation is the final step in genetic information flow (Figures 6.1a and 6.5), some proteins require subsequent *processing* or *targeting* before they become functional. These activities often require accessory proteins to assist with folding and transport as well as intrinsic signals within the translated protein itself.

6.11 Assisted Protein Folding and Chaperones

In Section 6.7 we saw how proteins show several levels of structure including primary, secondary, tertiary, and, in multi-subunit proteins, quaternary structure. Many proteins fold spontaneously into their active form, even while they are being synthesized (Figure 6.38). However, some do not, and these require assistance to achieve an active functional state.

Major Chaperones of *Bacteria*

Bacteria produce a series of proteins called **chaperones** that catalyze a variety of macromolecular folding events. These events include folding proteins that do not fold spontaneously, refolding partially denatured proteins, assembling multiprotein complexes, preventing the improper aggregation of proteins, untangling RNAs, and incorporating cofactors into enzymes. Chaperones are found in all domains of life, and their amino acid sequences are highly conserved among all organisms.

Four key chaperones in *Escherichia coli* are the proteins DnaK, DnaJ, GroEL, and GroES. DnaK and DnaJ are ATP-dependent enzymes that bind to newly formed polypeptides and prevent them from folding too quickly, which would increase the risk of improper folding (Figure 6.40a). If the DnaKJ complex is unable to fold the protein properly, it may transfer the partially folded protein to the two multi-subunit proteins GroEL and GroES. The protein first enters GroEL, a large, barrel-shaped protein that uses the energy of ATP hydrolysis to fold the protein properly. GroES assists in this (Figure 6.40a). It is estimated that about 100 of the several thousand different proteins in a cell of *E. coli* need help from the GroEL–GroES complex to become properly folded, and of these, a dozen or so are proteins essential for the survival of the bacterium.

Other Functions of Chaperones

Chaperones can also refold proteins that have partially denatured in the cell. A protein may denature for many reasons, but often it is because the organism has temporarily experienced high temperatures. Chaperones are thus one type of *heat shock protein*, and their synthesis is greatly accelerated when a cell is stressed by excessive heat (► Section 7.11). The heat shock response is an attempt by the cell to refold its partially denatured proteins for reuse before proteases recognize them as improperly folded and destroy them. In contrast to heat shock proteins, *cold shock proteins* are produced when the cell experiences a sudden shift to very cold temperatures. Cold (but nonfreezing) conditions do not affect most proteins but can affect RNAs. CspA, a major cold shock protein of *E. coli*, is an RNA chaperone instead of a protein chaperone and prevents the spontaneous formation of secondary structures in mRNA that could compromise their ability to be translated. Many other cold shock proteins are known in *E. coli* including ones that refold cold-sensitive proteins rather than acting on mRNAs.

Some chaperones help assemble cofactor-containing enzymes such as those that catalyze redox or electron transport reactions (◄ Section 3.8). For example, several multi-subunit molybdoenzymes such as the *E. coli* membrane-bound nitrate reductase (◄ Section 3.10 and Figure 3.23b) require that a molybdenum cofactor (Moco) be inserted during folding, and cofactor insertion is assisted by enzyme-specific chaperone proteins (Figure 6.40b). Nitrate reductase is a key enzyme in anaerobic respiration (◄ Section 3.10 and ► Section 14.11) and is composed of three subunits: NarG, NarH, and NarI. For the enzyme to be functional, the cytoplasmic chaperone protein NarJ must first insert the Moco

Figure 6.40 The activity of chaperone proteins. (a) An improperly folded protein can be refolded by either the DnaKJ complex or by the GroEL–GroES complex. In both cases, energy for refolding comes from ATP. Inset: Crystal structure of GroEL complex. (b) Formation of an active nitrate reductase enzyme (◀ Section 3.10 and Figure 3.23b) by chaperone-facilitated incorporation of a cofactor. The chaperone protein NarJ carries the molybdenum cofactor (Moco) to the inactive cytoplasmic NarGH complex. After incorporation of Moco, NarJ dissociates and the complex binds to NarL in the membrane, becoming an active enzyme.

group into NarG. Once this cofactor has been inserted, the NarG and NarH subunits associate with the membrane-bound NarL subunit to form the active nitrate reductase enzyme complex (Figure 6.40b).

- What macromolecules are protected by heat shock proteins?
- How do chaperones assist the *Escherichia coli* cell to make nitrate reductase?

6.12 Protein Secretion: The Sec and Tat Systems

While many proteins exist in the cell's cytoplasm, some must be transported outside the cytoplasmic membrane into the periplasm (of gram-negative cells) or inserted into the cytoplasmic or outer membranes to facilitate nutrient transport or bioenergetic events. Other proteins such as toxins and extracellular enzymes (exoenzymes) must be secreted from the cell entirely to be active in the environment or to invade another cell. These secreted proteins must get from their site of synthesis on ribosomes into or through the cytoplasmic membrane in order to be functional, and the cell has evolved several systems that require either ATP (or GTP) or the proton motive force (Chapter 3) to get this job done.

One example of an unusually large protein that must be secreted to perform its function is halomucin. Halomucin is produced by the halophilic archaeon *Haloquadratum walsbyi* and shares a structural similarity with animal mucin, which protects eyes and bronchial epithelium from dehydration. Thus halomucin is believed to protect *H. walsbyi* from desiccation when growing in its highly saline brine pool habitat (◀ Section 4.15). At 9159 amino acids, halomucin is one of the largest proteins produced by any life form (the average cellular protein is <500 amino acids). For this large protein to confer protection to *H. walsbyi*, the cell

must specifically recognize halomucin in the cytoplasm and orchestrate its secretion across the cytoplasmic membrane (Figure 6.41). While little is known about the mechanisms *H. walsbyi* uses to secrete proteins, however this is accomplished, a significant energy input would be needed to secrete a protein the extreme size of halomucin.

The Signal Sequence

Proteins called *translocases* transport specific proteins into or through the membranes of *Bacteria* and *Archaea*. For example, the Sec translocase system both exports unfolded proteins and inserts integral

Zenke, R. et al. 2015. *Frontiers in Microbiology* 6: 249

Figure 6.41 Secretion of halomucin. Fluorescent micrograph illustrating secreted halomucin (labeled with green fluorescent protein, ► Section 12.5) by the archaeon *Haloquadratum walsbyi* (red). Note that cells of *H. walsbyi* are square and are visualized here by using a red stain for storage polymers (poly- β -hydroxyalkanoates; ◄ Section 2.7).

membrane proteins into the cytoplasmic membrane. By contrast, the Tat translocase system transports previously folded proteins through the cytoplasmic membrane. Both the general secretion (Sec) and Tat systems are universal in *Bacteria* and *Archaea*.

Most proteins that must be transported into or through bacterial or archaeal cytoplasmic membranes are synthesized with an amino acid sequence of 15–20 residues—called the **signal sequence**—at the beginning (N-terminus, Figure 6.28) of the protein molecule. Signal sequences are variable, but they typically contain a few positively charged amino acids at the beginning, a central region of hydrophobic residues, and then a more polar region at their end. The signal sequence is so named because it “signals” to a translocase system that this particular protein is to be exported and also helps

prevent the protein from completely folding, a process that could interfere with its secretion. Because the signal sequence is the first part of the protein to be synthesized, the early steps in export may actually begin before the protein is completely synthesized (Figure 6.42).

Sec and Tat Translocases

In the Sec system, unfolded proteins to be exported from the cytoplasm are recognized by either the *SecA* protein or the *signal recognition particle* (SRP) (Figure 6.42). Typically, SecA binds polypeptides that are to be exported into the periplasm and transports the unfolded polypeptide to a membrane-bound channel. The polypeptide is then translocated through the channel using ATP as the energy source. Conversely, the SRP binds polypeptides that are to be inserted into the membrane (but not released on the other side) through a process called *cotranslation*. The bacterial SRP, which consists of a single protein and a small, noncoding RNA molecule (4.5S RNA), coordinates to both recognize polypeptides that are destined for the membrane and to move the ribosome actively translating these proteins to the membrane surface. Thus during cotranslation, the polypeptide is actively translated into the membrane, driven by the hydrolysis of GTP. After the protein has been inserted into the membrane (SRP-mediated) or has crossed the membrane (SecA-mediated), the signal sequence is removed by a protease and the proteins fold to their active form.

Some proteins must be folded before they are translocated because they contain cofactors that must be inserted as the protein folds; for example, iron–sulfur proteins, cytochromes, and other respiratory enzymes (◄ Section 3.8). Such proteins are processed by the Tat translocase system (for example, nitrate reductase shown in Figure 6.40b). Tat stands for “twin-arginine translocase” because the transported proteins contain a short signal sequence that has a pair of arginine residues. This signal sequence is recognized by TatBC, which carries the folded protein to TatA—the membrane transporter. Following transport, which is fueled by the proton-motive force, the signal sequence is removed by a protease.

Figure 6.42 Export of proteins via the SecA secretory system. The signal sequence is recognized either by SecA or by the signal recognition particle, which carries the protein to the membrane secretion system. The signal recognition particle binds proteins that are inserted into the membrane, whereas SecA binds proteins that are secreted across the cytoplasmic membrane.

Check Your Understanding

- What is the signal sequence and what does it signal?
- What is the signal recognition particle composed of?
- How do the translocases Sec and Tat differ in the molecules they secrete?

6.13 Protein Secretion: Gram-Negative Systems

In order to insert proteins or other small molecules known as *effectors* into the outer membrane of gram-negative *Bacteria*, or to secrete them outside of the cell, special secretion systems known as types I through VI are used. Proteins secreted by these systems are in their final folded form once outside of

the cell. Gram-positive bacteria and *Archaea* possess secretion systems similar to some of these, but in these organisms, the machinery only has to transport the proteins or effector molecules across the cytoplasmic membrane.

Types I–VI secretion systems facilitate several cellular activities including symbiotic interactions, biofilm formation, extracellular enzyme secretion, transfer of DNA, release of antibiotics, and delivery of proteins into host cells. Thus, molecules secreted by these systems allow bacteria to interact with the environment and other organisms. Each of these systems specifically recognizes its substrate based on amino acid residues and is composed of a large complex of proteins that forms a translocase channel spanning one or more membranes through which the secreted molecule travels (Figure 6.43).

Types II and V Secretion Systems

Secretion systems can be grouped into *one-step* and *two-step* classes. Type II and type V systems are two-step translocases because they depend on either the Sec or Tat system (Section 6.12) to transport the secreted protein or a portion of the translocase channel from the cytoplasm through the inner membrane (Figure 6.43a).

Type II systems are found in a wide variety of gram-negative pathogenic and nonpathogenic bacteria, and they transport proteins from the periplasm to the extracellular environment. The translocase machinery of type II systems includes a secretion pore in the outer membrane that is anchored to the cytoplasmic membrane by proteins that span the periplasm (Figure 6.43a). While the type II

system does possess cytoplasmic membrane and periplasmic components, proteins to be secreted do not translocate through these and are instead delivered to the secretion pore in the outer membrane by either the Sec or Tat system. A key to the specificity of the type II system is that the secretion pore only opens to proteins specific to the type II system. Examples of proteins secreted by a type II system include the toxin produced by *Vibrio cholerae* (the causative agent of cholera) and a glucanase exoenzyme produced by *Klebsiella pneumoniae* to degrade large extracellular starch molecules.

Type V systems are the structurally simplest of the secretion systems (Figure 6.43a) and are also called *autotransporters* in that the protein to be secreted is fused to a transmembrane protein domain essential to the protein's transport across the outer membrane. After this unfolded multidomain protein is itself transported through the cytoplasmic membrane by the Sec system, a transmembrane domain called the transporter forms a secretion pore in the outer membrane that allows the remainder of the protein (the passenger domain) to pass through and ultimately be secreted outside of the cell (Figure 6.43a). Thus proteins to be moved outside of the cell by a type V system are initially transported in the unfolded state, and both the transporter and passenger domains require chaperone proteins (Section 6.11) for proper folding. The folding of the passenger domain (instead of ATP hydrolysis) drives type V secretion. Examples of proteins secreted by the type V system are adhesion proteins used by *Escherichia coli* and *Haemophilus influenzae* (a causative agent of pneumonia) to attach to host cells.

Figure 6.43 Secretion systems in gram-negative bacteria. (a) Types I, II, and V secrete proteins outside of the bacterial cell. Type I systems secrete proteins in a single step. Types II and V first require the Sec or Tat system to transport the protein to be secreted across the inner membrane. Note that during type V secretion, the Sec system first transports the unfolded transporter domain linked to the unfolded secretion protein through the inner membrane. The translocase then folds in the outer membrane and delivers the folded secretion protein through the outer membrane. (b) Types III, IV, and VI secrete molecules outside of the bacterial cell and into a host cell. Type III systems have been termed the injectisome, (see page 201) while type IV systems are similar to a pilus (Section 2.6) and also secrete DNA into a host cell. Type VI systems contain a sheath or needle in the cytoplasm that contracts to deliver a protein into a host cell.

Types I, III, IV, and VI Secretion Systems

The second class of translocases moves proteins through the outer membrane in a single step. Types I, III, IV, and VI are one-step systems because they form channels through both the cytoplasmic and outer membranes and do not require Sec or Tat. *Type I systems* are ABC transporters (◀ Section 2.2) that are characterized by three protein components: (1) a cytoplasmic membrane transporter coupled to (2) an outer membrane pore by (3) a membrane fusion protein. The cytoplasmic membrane transporter binds specifically to the protein to be secreted and requires ATP to initiate transport to the outside of the cell (Figure 6.43a). While the cytoplasmic membrane transporter is specific to its substrate, a wide range of polypeptide sizes can be secreted. Type I systems secrete small molecules such as a toxic protein (bacteriocin) produced by *E. coli* to kill competing bacterial cells and can also secrete large proteins such as those necessary for biofilm formation on plant surfaces by the soil bacterium *Pseudomonas fluorescens*.

Type III systems are commonly used by pathogenic bacteria not only to secrete toxic proteins outside of the cell but to inject these molecules directly into eukaryotic host cells (Figure 6.43b). The entire type III structure is highly complex and composed of over 100 proteins that facilitate substrate recognition, coordinated assembly of the machinery for translocations, and the transport process itself. ATP hydrolysis provides the energy for the secretion and injection. The entire structure, 30–70 nm in length, has been termed the “injectisome” for its similarity to a syringe in both structure and function (Figure 6.44a and page 201). Proteins injected into host cells by the type III system often aid in pathogen infection and host invasion. Type III-injected proteins include certain effector molecules of *Chlamydia* (the cause of trachoma and a sexually transmitted disease) and *Salmonella* (a foodborne and waterborne pathogen). However, type III secretion systems are not limited to pathogens. Nitrogen-fixing bacteria deliver molecules critical for establishing a symbiotic relationship with plant roots (root nodules) through type III secretion machinery (▶ Section 23.4).

Type IV systems (Figure 6.43b) are the most ubiquitous and are present in many *Bacteria* and *Archaea*. This system is also used to deliver secreted proteins or other molecules *into* other cells. While this system can be used to transport toxins into host cells, its primary role is to transfer DNA to other cells through the process of conjugation (▶ Section 9.8), one mechanism that prokaryotic cells have to

exchange genes. The type IV translocase is similar to a pilus that extends through the outer membrane into another cell during conjugation. Once the tip of the pilus makes contact with a receptor on the host cell, the DNA is recognized by an inner membrane protein of the donor and then transferred using ATP-facilitated transport (▶ Section 9.8). Not only can DNA be transferred from one bacterial cell to another using a type IV system, DNA from the plant pathogenic bacterium *Agrobacterium* can be transferred to host plant cells through the system encoded on the Ti plasmid (resulting in crown gall disease, ▶ Section 23.6).

Type VI systems are widely distributed in gram-negative bacteria, and like type IV systems they are capable of delivering a diversity of proteins directly into the cytoplasm of other cells using a one-step, ATP-requiring process similar to type III and IV systems. However, unlike the injectisome or pilus-like structure of the type III and IV translocase systems, the type VI translocase is cytoplasmic and forms a needle-like protein with a pore-forming protein that contracts all the way through the donor cell’s two membranes and directly into a host cell once a substrate molecule is recognized (Figures 6.43b and 6.44b). The overall delivery process is similar to the mechanism that the tailed bacteriophage T4 uses to deliver DNA into an *E. coli* cell through tail contraction (◀ Section 5.5). Type VI systems are used by bacteria as weapons to compete with other bacterial cells or to attack eukaryotic cells. In *Pseudomonas aeruginosa*, a type VI system is used to inject a toxin into competing bacterial cells. Similarly, *Vibrio cholerae* uses its type VI system (Figure 6.44b) to inject enzymes into competing bacteria; the enzymes degrade the cell wall and membrane. *V. cholerae* also uses the system to deliver toxins to human intestinal cells during a cholera infection.

It should be obvious by now that protein secretion is a crucial aspect of the biology of *Bacteria* and *Archaea* and that these cells have evolved diverse structures and unique mechanisms to deal with protein secretion. In fact, three other systems (types VII–IX) have also been discovered, but their mechanisms have not been fully described. All of these elaborate systems are of interest for reasons beyond basic science. Since many of these systems are essential virulence factors (▶ Section 25.3) for the pathogenic bacteria that produce them, they are currently targets for vaccine development. The rationale here is quite simple: If the activity of these systems could be blocked by the immune system, the pathogen would be unable to establish an infection and cause disease.

We now move on from our focus on the central dogma of biology, protein processing, and protein secretion to tackle the concepts of Chapter 7, where we will examine how gene expression and protein activity are regulated. Without regulatory systems, cells would not be able to quickly respond to ever-changing conditions in their environments, and thus their very survival would be at stake.

Check Your Understanding

- Compared with gram-positive bacteria, why is it important for gram-negative bacteria to have additional secretion pathways?
- How do the types I–VI secretion processes differ from Sec and Tat secretion?
- Why is the injectisome so named?

Figure 6.44 Electron micrographs of secretion machinery. (a) Purified type III injectisomes from *Salmonella enterica* (*typhimurium*) (see also page 201). (b) Purified type VI contractile sheaths from *Vibrio cholerae*.

CHAPTER REVIEW

for videos, animations, practice tests, and more.

I • Molecular Biology and Genetic Elements

- 6.1** The informational content of a nucleic acid is determined by the sequence of nitrogenous bases along the polynucleotide chain. Both RNA and DNA are informational macromolecules, as are the proteins they encode. DNA forms a double-stranded helix whose strands are complementary and antiparallel. DNA is supercoiled before it is packaged into cells. The three key processes of macromolecular synthesis are: (1) DNA replication; (2) transcription (RNA synthesis); and (3) translation (protein synthesis).

Q Describe the central dogma of molecular biology. With regards to DNA, what is supercoiling and what is meant by the terms antiparallel and complementary?

- 6.2** In addition to the chromosome, other genetic elements can exist in cells. Plasmids are DNA molecules that exist separately from the chromosome and may confer a selective growth advantage under certain conditions. Viruses contain an RNA or DNA genome, and transposable elements exist as a part of other genetic elements.

Q How are chromosomes and plasmids similar, and how do they differ? What are R plasmids and why are they of medical concern?

II • Copying the Genetic Blueprint: DNA Replication

- 6.3** Both strands of the DNA helix are templates for the synthesis of new strands (semiconservative replication). The new strands are elongated by addition of deoxyribonucleotides to the 3' end. DNA polymerases require a primer made of RNA by the enzyme primase, and synthesis begins at an origin of replication. The double helix is unwound by helicase and is stabilized by single-strand binding proteins. Extension of the DNA occurs continuously on the leading strand but discontinuously on the lagging strand, resulting in fragments that must be joined together.

Q What is meant by the term semiconservative replication? What are the functions of DNA Pol I and III, helicase, and primase? How does a leading strand differ from a lagging strand?

- 6.4** Starting from a single origin on a circular chromosome, two replication forks synthesize DNA simultaneously in both directions until the forks meet at the terminus region. The proteins at the replication fork form a large complex known as the replisome. Most errors in base pairing that occur during replication are corrected by the proofreading functions of DNA polymerases.

Q What is the replisome and what does it contain? Why can replication occur faster on circular DNA than on linear DNA? What is proofreading and why is it important?

III • RNA Synthesis: Transcription

- 6.5** In *Bacteria*, promoters are recognized by the sigma subunit of RNA polymerase. Alternative sigma factors allow joint regulation of large families of genes in response to growth conditions. Transcription by RNA polymerase continues until specific sites called transcription terminators are reached. These terminators function at the level of RNA. In *Bacteria* and *Archaea* a single mRNA molecule may encode more than one polypeptide. A cluster of genes that are transcribed together from a single promoter is called an operon.

Q What do promoters do in *Bacteria*? How is a transcript in *Bacteria* terminated?

- 6.6** The transcription apparatus and the promoter architecture of *Archaea* and *Eukarya* have many features in common, although the components are usually relatively more simple in *Archaea*. In contrast, the processing of eukaryotic primary transcripts is unique and has three distinct steps: splicing, capping, and adding a poly(A) tail.

Q How does the archaeal RNA polymerase differ from that in *Bacteria*? How does the initiation of transcription in the two domains differ? Why do eukaryotic mRNAs have to be "processed" whereas most prokaryotic RNAs do not?

IV • Protein Synthesis: Translation

- 6.7** Polypeptide chains contain many amino acids linked via peptide bonds. Twenty-two different amino acids are genetically encoded. The primary structure of a protein is its amino acid sequence, but the higher-order structure (folding) of the polypeptide determines its cellular function.

Q Describe the two types of secondary structure a polypeptide can attain. Which proteins can achieve quaternary structure? Which protein structure(s) are altered by denaturation?

- 6.8** One or more tRNAs exist for each amino acid incorporated into polypeptides by the ribosome. Enzymes called aminoacyl-tRNA synthetases bond amino acids to their cognate tRNAs.

Q Why are tRNAs important in translation? Do genes for tRNAs have promoters, and are tRNAs translated? What are aminoacyl-tRNA synthetases, what are their substrates, and what do they do?

- 6.9** The genetic code is expressed as RNA, and a single amino acid may be encoded by several different but related codons. In addition to the stop (nonsense) codons, there is also a specific start codon that signals the initiation of translation.

Q Why is the genetic code a degenerate code? What is wobble and how does it accommodate fidelity in the genetic code?

6.10 Translation occurs on the ribosome and requires mRNA and aminoacyl-tRNAs. The ribosome has three sites: acceptor, peptide, and exit (A, P, and E). During each step of translation, the ribosome advances one codon along the mRNA, and the tRNA in the acceptor site moves to the peptide site. Protein synthesis terminates when a stop codon, which does not have a corresponding tRNA, is reached.

Q Where on the ribosome do tRNAs bind, and what is the energy source that supports translocation?

V • Protein Processing, Secretion, and Targeting

6.11 Polypeptides do not remain linear in structure following translation but require proper folding and additional processing for functional activity. Proteins called chaperones help fold some proteins that are unable to fold spontaneously and also assist in the incorporation of cofactors and refolding partially denatured proteins.

Q What is the primary function of chaperones? How do cells sometimes reuse partially denatured proteins?

6.12 Many proteins need to be transported into or through the cytoplasmic membrane. These proteins contain a signal sequence that is recognized by the cellular translocase systems of Sec and Tat.

Q What are the functions of the Sec and Tat systems and why are they necessary? How do these systems know which proteins to act upon?

6.13 A large diversity of secretion systems are employed by gram-negative bacteria to secrete proteins into or through their outer membrane and even into other cells, and types I–VI secretion systems function in this regard. Types II and V are two-step translocases and rely on the activity of Sec or Tat, whereas types I, III, IV, and VI are one-step translocases. In most cases, energy is required to drive secretion of proteins outside the cell.

Q What are the major differences between one-step and two-step translocases? Which are used to secrete proteins into other cells?

APPLICATION QUESTIONS

1. The genome of the bacterium *Neisseria gonorrhoeae* consists of one double-stranded DNA molecule that contains 2220 kilobase pairs. If 85% of this DNA molecule is made up of the open reading frames of genes encoding proteins, and the average protein is 300 amino acids long, how many protein-encoding genes does *Neisseria* have? What kind of genetic information is present in the other 15% of the DNA?
2. Compare and contrast the activity of DNA and RNA polymerases. What is the function of each? What are the substrates of each? What is the main difference in the behavior of the two polymerases?
3. What would be the result (in terms of protein synthesis) if RNA polymerase initiated transcription one base upstream of its normal starting point? Why? By inspecting Table 6.4, discuss how the genetic code has evolved to help minimize the impact of mutations.

CHAPTER GLOSSARY

Amino acid one of the 22 different monomers that are attached to one another by peptide bonds to form proteins; chemically, a two-carbon carboxylic acid containing an amino group and a characteristic substituent on the alpha carbon

Aminoacyl-tRNA synthetase an enzyme that catalyzes attachment of an amino acid to its cognate tRNA

Anticodon a sequence of three bases in a tRNA molecule that base-pairs with a codon during protein synthesis

Antiparallel in reference to double-stranded DNA, the two strands run in opposite directions (one runs 5' → 3' and the complementary strand 3' → 5')

Bacteriocin a toxic protein secreted by bacteria that inhibits or kills other, related bacteria

Chaperone a protein that helps other proteins fold or refold from a partly denatured state

Chromosome a genetic element, usually circular in prokaryotic cells, carrying genes essential to cellular function

Codon a sequence of three bases in mRNA that encodes an amino acid

Codon bias the nonrandom usage of multiple codons encoding the same amino acid; the relative proportions of different codons encoding the same amino acid vary in different organisms. Same as codon usage

Complementary nucleic acid sequences that can base-pair with each other

Denaturation loss of the correct folding of a protein, leading (usually) to protein aggregation and loss of biological activity

DNA (deoxyribonucleic acid) a polymer of deoxyribonucleotides linked by phosphodiester bonds; the deoxyribonucleotide sequence encodes genetic information

DNA gyrase an enzyme found in *Bacteria* and most *Archaea* that introduces negative supercoils in DNA

DNA helicase an enzyme that uses ATP to unwind the double helix of DNA

DNA ligase an enzyme that seals nicks in the backbone of DNA

DNA polymerase an enzyme that synthesizes a new strand of DNA in the 5' → 3' direction using an antiparallel DNA strand as a template

Exons the coding DNA sequences in a split gene (contrast with intron)

Gene a segment of DNA specifying a protein (via mRNA), a tRNA, an rRNA, or any other noncoding RNA

Genetic code the correspondence between nucleic acid sequence and amino acid sequence of proteins

Genetic element a structure that carries genetic information, such as a chromosome, a plasmid, or a virus genome

Genome the total complement of genes contained in a cell or virus

Informational macromolecule any large polymeric molecule that carries genetic information, including DNA, RNA, and protein

Introns the intervening noncoding DNA sequences in a split gene (contrast with exons)

Lagging strand the new strand of DNA that is synthesized in short pieces and then joined together later

Leading strand the new strand of DNA that is synthesized continuously during DNA replication

Messenger RNA (mRNA) an RNA molecule that contains the genetic information to encode one or more polypeptides

Nonsense codon another name for a stop codon

Nucleoside a nitrogenous base (adenine, guanine, cytosine, thymine, or uracil) plus a sugar (either ribose or deoxyribose) but lacking phosphate

Nucleotide a monomer of a nucleic acid containing a nitrogenous base (adenine, guanine, cytosine, thymine, or uracil), one or more molecules of phosphate, and a sugar, either ribose (in RNA) or deoxyribose (in DNA)

Open reading frame (ORF) a sequence of DNA or RNA that could be translated to give a polypeptide

Operon two or more genes transcribed into a single RNA and under the control of a single regulatory site

Peptide bond a type of covalent bond linking amino acids in a polypeptide

Phosphodiester bond a type of covalent bond linking nucleotides together in a polynucleotide

Plasmid an extrachromosomal genetic element that is usually not essential to the cell

Polynucleotide a polymer of nucleotides bonded to one another by covalent bonds called phosphodiester bonds

Polypeptide a polymer of amino acids bonded to one another by peptide bonds

Primary structure the precise sequence of monomers in a macromolecule such as a polypeptide or a nucleic acid

Primary transcript an unprocessed RNA molecule that is the direct product of transcription

Primase the enzyme that synthesizes the RNA primer used in DNA replication

Primer an oligonucleotide to which DNA polymerase attaches the first deoxyribonucleotide during DNA synthesis

Promoter a site on DNA to which RNA polymerase binds to commence transcription

Protein a polypeptide or group of polypeptides forming a molecule of specific biological function

Purine one of the nitrogenous bases of nucleic acids that contain two fused rings; adenine and guanine

Pyrimidine one of the nitrogenous bases of nucleic acids that contain a single ring; cytosine, thymine, and uracil

Quaternary structure in proteins, the number and types of individual polypeptides in the final protein molecule

Replication in cells, synthesis of DNA using DNA as a template

Replication fork the site on the chromosome where DNA replication occurs and where the enzymes replicating the DNA are bound to untwisted, single-stranded DNA

Replisome a DNA replication complex that consists of two copies of DNA polymerase III, DNA gyrase, helicase, primase, and copies of single-strand binding protein

Ribosomal RNA (rRNA) the types of RNA found in the ribosome; some participate actively in protein synthesis

Ribosome a cytoplasmic particle composed of ribosomal RNA and protein, whose function is to synthesize proteins

RNA (ribonucleic acid) a polymer of ribonucleotides linked by phosphodiester bonds that plays many roles in cells, in particular, during protein synthesis

RNA polymerase an enzyme that synthesizes RNA in the 5' → 3' direction using a complementary and antiparallel DNA strand as a template

RNA processing the conversion of a primary transcript RNA to its mature form

Secondary structure the initial pattern of folding of a polypeptide or a polynucleotide, usually dictated by opportunities for hydrogen bonding

Semiconservative replication DNA synthesis yielding two new double helices, each consisting of one parental and one progeny strand

Signal sequence a special N-terminal sequence of approximately 20 amino acids that signals that a protein should be incorporated into or exported across the cytoplasmic membrane

Spliceosome a complex of ribonucleoproteins that catalyze the removal of introns from primary RNA transcripts

Start codon a special codon, usually AUG, that signals the start of a protein

Stop codon a codon that signals the end of a protein

Termination stopping the elongation of an RNA molecule at a specific site

Tertiary structure the final folded structure of a polypeptide that has previously attained secondary structure

Transcription the synthesis of an RNA molecule complementary to one of the two strands of a double-stranded DNA molecule

Transfer RNA (tRNA) a small RNA molecule used in translation that possesses an anticodon at one end and has the corresponding amino acid attached to the other end

Translation the synthesis of protein by a ribosome using the genetic information in a messenger RNA as a template

Transposable element a genetic element able to move (transpose) from one site to another on host DNA molecules

Wobble a less rigid form of base pairing allowed only in codon-anticodon pairing

MICROBIOLOGYNOW

As Bacterial Cells Chatter, Viruses Eavesdrop

Despite their primitive nature, bacterial and archaeal cells participate in a form of communication called quorum sensing. Quorum sensing coordinates behaviors that require a certain cell density to be successful, such as virulence and biofilm formation. This communication is dependent on the microbial secretion of autoinducer molecules. As the population of autoinducer-producing cells increases in a given environment, so does the local concentration of autoinducer. Once the autoinducer reaches a certain threshold, regulatory proteins respond by activating genes whose products are necessary for group behavior.

As extensive research on quorum sensing continued, microbiologists began to ponder if viruses could respond to quorum sensing. Temperate bacteriophages have two possible “lifestyles”—their DNA can reside in dormancy within the bacterial host cell chromosome or they can aggressively multiply and lyse their host cell. Using elegant experiments, researchers discovered that certain dormant bacteriophages are actually “listening in” on their hosts’ conversation. This eavesdropping occurs through a

phage-encoded receptor protein that can sense host autoinducer concentrations. In response to autoinducer concentrations, this phage regulatory protein initiates a cascade of events that awakens the phage from dormancy.

The image to the left shows *Escherichia coli* cells harboring a fluorescently labeled phage repressor protein called *cl* that is distributed uniformly throughout the host cell and is essential for phage dormancy. The panel on the right shows the same cells with the addition of the newly discovered phage-encoded protein called Qtip, which is only produced in response to high autoinducer levels. Qtip functions by inactivating the *cl* protein by aggregating it (bright foci in right panel). Without free *cl*, the dormant phage produces thousands of progeny and lyses its host. This fascinating phenomenon illustrates how a nonliving microbe—the virus—both senses and responds to host cell communication to ensure its own successful spread!

To efficiently orchestrate the numerous reactions that occur in a cell and to maximally use available resources, cells must *regulate* the types, amounts, and activities of proteins and other macromolecules they make. Some proteins and RNA molecules are needed in the cell at about the same level under all growth conditions, and the production of these molecules is said to be *constitutive*. However, many proteins and RNAs are needed under some conditions but not others. For instance, enzymes required to catabolize the sugar lactose are useful only if lactose is available to the cell. Regulatory systems can thus be viewed as a means to improve the overall fitness of an organism and maximize its ability to produce offspring from the resources available.

Microbes regulate protein function in two distinct ways. One mechanism controls the *amount* of an enzyme or other protein, whereas the second controls the *activity* of a preformed enzyme or other protein (**Figure 7.1**). The amount of protein synthesized can be regulated at either the level of *transcription*—by varying the amount of mRNA made—or the level of *translation*—by translating or not translating the mRNA. Collectively, these regulatory processes are called **gene expression**. After a protein has been synthesized, *post-translational* regulatory processes can further regulate the activity of

some proteins (Figure 7.1). In this chapter we focus on how the cell efficiently controls its metabolism by regulating both enzyme synthesis and enzyme activity.

I • DNA-Binding Proteins and Transcriptional Regulation

Transcriptional controls in *Bacteria* and *Archaea* typically function by binding a specific regulatory protein to a specific region of DNA, an event that either represses or activates transcription.

Although several microbial regulatory mechanisms are possible, our discussion begins with control at the level of transcription because this is the major means of regulation in prokaryotic cells.

7.1 DNA-Binding Proteins

Before delving into the themes of transcriptional regulation, we must first recall our discussion of how bacterial and archaeal gene

Figure 7.1 Gene expression and regulation of protein activity. For DNA, the promoter and terminator as well as regions related to transcriptional activation and repression are indicated. Cellular signals control the activity and DNA-binding ability of activator and repressor proteins. For mRNA, the 5' untranslated region (5'-UTR) is a short region between the start of transcription and the start of translation, including the ribosome-binding site (RBS). The 3' untranslated region (3'-UTR) is a short region between the stop codon and the transcription terminator. These are the regions where translational regulation often occurs, with riboswitches and small RNAs (sRNAs) often targeting the 5'-UTR in response to cellular signals. Mechanisms for regulating protein activity after translation are shown near the bottom.

arrangement differs from that of eukaryotes (Chapter 6). Besides lacking traditional introns, bacterial and archaeal genes can be arranged in **operons**—two or more genes transcribed under the control of a single regulatory site (◀ Section 6.5). This regulatory site, or *promoter region*, is located upstream of where RNA polymerase initiates transcription (Figure 7.1). Bacterial and archaeal promoter regions are characterized by distinct nucleotide sequences that must be recognized and bound by *DNA-binding proteins* for RNA polymerase to bind and allow transcription to occur (◀ Sections 6.5 and 6.6).

Interaction of Proteins with Nucleic Acids

Interactions between proteins and nucleic acids are central to replication, transcription, and translation, and also to the regulation of these processes. Protein–nucleic acid interactions may be specific or nonspecific, depending on whether the protein attaches anywhere along the nucleic acid or binds to a specific site. Most DNA-binding proteins interact with DNA in a sequence-specific manner. Specificity is provided by interactions between specific amino acid side chains of the proteins and specific chemical groups on the nitrogenous bases and the sugar–phosphate backbone of the DNA. Because of its size, the *major groove* of DNA (◀ Figure 6.3) is the main site of protein binding, and Figure 6.1c identified atoms of the bases in the major groove that are known to interact with proteins. To achieve high specificity, the binding protein must interact simultaneously with several nucleotides.

In DNA, an *inverted repeat* is a nucleotide sequence followed downstream by its inverted complement (◀ Section 6.5). Such inverted repeats are frequently the locations at which proteins bind specifically to DNA (Figure 7.2). Note that this interaction does not require the formation of stem–loop structures in the DNA as was described

for the signal for termination of transcription (◀ Figure 6.23). DNA-binding proteins are often homodimeric, meaning they are composed of two identical polypeptide subunits, each subdivided into **domains**—regions of the protein with a specific structure and function. Each subunit has a domain that interacts specifically with a region of DNA in the major groove. When protein dimers interact with inverted repeats on DNA, each subunit binds to one of the inverted repeats. The dimer as a whole thus binds to both DNA strands (Figure 7.2).

Structure of DNA-Binding Proteins

DNA-binding proteins in both *Bacteria* and *Archaea* as well as eukaryotes possess several classes of protein domains that are critical for proper binding to DNA. One of the most common is the *helix-turn-helix* structure (Figure 7.3a). This consists of two segments of polypeptide chain that have an α -helix secondary structure connected by a short sequence forming the “turn.” The first helix is the *recognition helix*, which interacts specifically with DNA. The second helix, the *stabilizing helix*, stabilizes the first helix by interacting with it by way of hydrophobic interactions. The turn linking the two helices consists of three amino acid residues, the first of which is typically a glycine. Sequences are recognized by noncovalent interactions, including hydrogen bonds and van der Waals contacts, between the recognition helix of the protein and specific chemical groups in the sequence of base pairs on the DNA.

Many different DNA-binding proteins from *Bacteria* contain the helix-turn-helix structure. These include many repressor proteins, such as the *lac* and *trp* repressors of *Escherichia coli* (Section 7.3 and Figure 7.3 inset), and some proteins of bacterial viruses, such as the bacteriophage lambda repressor (Figure 7.3b). Indeed, over 250 different proteins with this motif bind to specific locations on DNA to regulate transcription in *E. coli*. Two other types of protein domains are commonly found in DNA-binding proteins. One of these, the *zinc finger*, is frequently found in regulatory proteins in eukaryotes and, as its name implies, binds a zinc ion. The other protein domain commonly found in DNA-binding proteins is the *leucine zipper*, which contains regularly spaced leucine residues that function to hold two recognition helices in the correct orientation to bind DNA.

Once a protein binds at a specific site on the DNA, several outcomes are possible. Some DNA-binding proteins are enzymes that catalyze a specific reaction on the DNA, such as transcription. In other cases, however, the binding event either blocks transcription or activates it, and we consider these now.

Check Your Understanding

- What is a protein domain?
- Why are most DNA-binding proteins specific to certain chemical groups within the DNA?

Figure 7.2 DNA-binding proteins. Many DNA-binding proteins are dimers that combine specifically with two sites on the DNA. The specific DNA sequences that interact with the protein are inverted repeats. The nucleotide sequence of the operator gene of the lactose operon (see Figure 7.6) is shown, and the inverted repeats, which are sites at which the *lac* repressor (LacI) makes contact with the DNA, are shown in purple and blue boxes.

7.2 Transcription Factors and Effectors

Transcription is the first step in biological information flow; because of this, it is simple and efficient to control gene expression at this point. If one gene is transcribed more frequently than another, there will be more of its mRNA available for translation and therefore a

Figure 7.3 The helix-turn-helix structure of some DNA-binding proteins. (a) A simple model of the helix-turn-helix structure within a single protein subunit. (b) A computer model of both subunits of the bacteriophage lambda repressor bound to its operator. The complementary DNA strands are red and blue. One subunit of the dimeric repressor protein is shown in orange and the other in yellow. Each subunit contains a helix-turn-helix structure. Inset: Atomic force microscopy showing copies of the LacI repressor protein (arrow) bound to multiple operator sites on a DNA molecule.

greater amount of its protein product in the cell. This control is mediated by *transcription factors* and *effector molecules*.

Mechanisms of Transcription Factors

Proteins that control the rate of gene transcription by binding to specific DNA sequences are called **transcription factors**. Depending on the type of transcription factor, this DNA binding can lead to increased or decreased transcription of the associated gene. If binding to the DNA results in turning transcription *on*, the transcription factor is called an **activator protein** (Figure 7.4a). Conversely, binding of a **repressor protein** to DNA results in turning gene expression *off* (Figure 7.4b).

Activator proteins turn on transcription by binding to DNA and helping to recruit RNA polymerase, or a sigma (σ) factor in the case of bacterial transcription (◀ Section 6.5), to a specific promoter region (Figure 7.4a). Repressor proteins turn off transcription by binding to a specific DNA sequence of a gene called an *operator* region (Figure 7.4b). This region gets its name from the *operon*, a cluster of consecutive genes whose expression is under the control of a single operator (◀ Section 6.2). All of the genes in an operon are transcribed as a single unit yielding a single mRNA (◀ Section 6.5). The operator is located downstream of the promoter where synthesis of mRNA is initiated (Figure 7.4). The activity of activator and repressor proteins is described in more detail in the next section.

Figure 7.4 Transcription factors, effectors, and allosterism. Binding of effector molecules to activator and repressor proteins results in an allosteric change that affects the DNA-binding ability of the transcription factors. (a) Binding of an activator to the DNA results in recruiting RNA polymerase and turning transcription on. (b) Binding of a repressor protein to the operator region of the DNA results in blocking RNA polymerase and turning transcription off.

Effector Molecules

The ability of activator and repressor proteins to bind DNA is controlled by small molecules called *effectors*. Transcription factors are **allosteric proteins**; that is, their conformation is altered when the effector molecule binds to them (Figure 7.4 and Section 7.15). This conformational change determines if the transcription factor can bind DNA. If the binding of an effector to a transcription factor results in turning transcription *on*, the molecule is considered an *inducer* (Figure 7.4a). Conversely, *corepressor* molecules are those whose binding to a transcription factor results in turning transcription *off* (Figure 7.4b).

Effector molecules are typically cell metabolites, such as substrates or end products of the pathways that they regulate. As we will discuss with the *lac* operon—the operon encoding genes of lactose catabolism—structural analogs of effector molecules can also control transcription factor binding even though they are not themselves substrates for the enzymes that the operon encodes (Section 7.8). Thus, small molecules can indirectly regulate gene expression by binding to transcription factors, as many examples in this chapter will demonstrate.

Check Your Understanding

- What is a transcription factor and what are the two major types?
- What role do effectors have on transcription factors?

7.3 Repression and Activation

The activities of activator and repressor proteins are simple forms of regulation that govern gene expression at the level of transcription, and the binding of these transcription factors to DNA plays the initial role in controlling the kinds and activities of enzymes in a cell. We begin our discussion of the activities of some common

transcription factors by considering cellular conditions in which the expression of particular sets of enzymes are controlled.

Enzyme Repression and Induction

Often the enzymes that catalyze the synthesis of a specific product are not made if the product is already present in the growth medium in sufficient amounts. For example, in *Escherichia coli* and many other *Bacteria*, the enzymes needed to synthesize the amino acid arginine (◀ Figure 6.27) are made only when arginine is *absent* from the culture medium; an excess of arginine decreases the synthesis of these enzymes. This is called **enzyme repression**.

As can be seen in Figure 7.5a, if arginine is added to a culture growing exponentially in a medium devoid of arginine, growth continues at the previous rate, but production of the enzymes for arginine synthesis stops. Note that this is a *specific* effect, as the synthesis of all other enzymes in the cell continues at the previous rate. This is because the enzymes affected by a particular repression event make up only a tiny fraction of the entire complement of proteins in the cell. Enzyme repression is widespread in *Bacteria* as a means of controlling the synthesis of enzymes required for the production of amino acids and the nucleotide precursor purines and pyrimidines (◀ Section 3.14). In most cases, the final product of a particular biosynthetic pathway is the effector molecule (corepressor) for that pathway and must be present in excess of biosynthetic needs to repress the enzymes of the pathway. Such enzyme repression ensures that the organism does not waste energy and nutrients synthesizing unneeded enzymes.

Enzyme induction is conceptually the opposite of enzyme repression. In enzyme induction, an enzyme is made only when its substrate is *present*. Enzyme repression typically affects biosynthetic (anabolic) enzymes. By contrast, enzyme induction usually affects the synthesis of specific degradative (catabolic) enzymes. To illustrate induction, consider the utilization of the sugar lactose as a carbon and energy source by *E. coli*. The enzymes for using lactose are

Figure 7.5 Enzyme repression and expression of the arginine operon. (a) In a growing bacterial culture, the addition of arginine to the medium specifically represses production of enzymes needed to make arginine. Net protein synthesis is unaffected. (b) The operon is transcribed because the repressor ArgR is unable to bind to the operator. (c) After the corepressor for the *argCBH* operon, the amino acid arginine, binds to the repressor, the repressor binds to the operator and blocks transcription; mRNA and the proteins it encodes are not made.

Figure 7.6 Enzyme induction and expression of the lactose operon. (a) In a growing bacterial culture, the addition of lactose to the medium specifically induces synthesis of the enzyme β -galactosidase and other proteins of lactose catabolism. Net protein synthesis is unaffected. (b) Binding of the LacI repressor protein to the operator blocks the activity of RNA polymerase. (c) Binding of the inducer molecule to the LacI repressor inactivates LacI so that it no longer can bind to the operator. This type of inducer binding results in derepression because RNA polymerase can now transcribe an mRNA for that operon. For the *lac* operon, the sugar allolactose rather than lactose is the actual inducer that binds to the LacI repressor.

encoded by the *lac* operon (Figure 7.6). Figure 7.6a shows the induction of β -galactosidase, the enzyme that cleaves lactose into glucose and galactose. This enzyme is required for *E. coli* to grow on lactose. If lactose is absent, the enzyme is not made, but synthesis begins almost immediately after lactose is added. The three genes in the *lac* operon encode three proteins, including β -galactosidase, that are induced simultaneously upon adding lactose. Such enzyme induction ensures that specific enzymes are synthesized only when needed.

Mechanisms of Repression and Derepression

As discussed in Section 7.2, repressor proteins that bind to DNA turn off transcription, and if a repressor binds DNA only in the presence of its effector, the effector is considered a corepressor. Figure 7.5b shows transcription of the arginine genes, which proceeds when the cell needs arginine. However, when arginine is plentiful, it becomes a corepressor. As Figure 7.5c shows, arginine binds to a specific repressor protein, the *arginine repressor* (ArgR), present in the cell. Binding of the corepressor to ArgR results in an allosteric change in this protein that allows it to bind to the operator. In this way, transcription is physically blocked because RNA polymerase can neither bind nor proceed, and in the absence of *arg* mRNA, the corresponding polypeptides encoded by the *arg* operon cannot be synthesized. If the mRNA is polycistronic (◀ Section 6.5), as the *arg* operon is, all the polypeptides encoded by this mRNA will be repressed (Figure 7.5c).

In contrast to the control of the *arg* operon, some repressor proteins actively bind to operator regions on the DNA in the *absence* of their effector molecule. Figure 7.6b shows the repression of the *lac* operon—an example of an inducible operon—by the binding of the lactose repressor (LacI) to the operator region. This binding of LacI completely blocks transcription. If the LacI effector molecule is present, it combines with the repressor protein, causing an allosteric change that prevents LacI from binding DNA; when this occurs,

inhibition is overcome and transcription can proceed (Figure 7.6c). Because control of inducible operons is the opposite of repression, it is also called *derepression*. The corresponding effector molecule (corepressor) in this case is called an *inducer* as its presence leads to inactivation of the repressor and ultimately enzyme synthesis.

For the *lac* operon example in Figure 7.6c, allolactose, an isomer made from lactose, is the actual inducer molecule that leads to the expression of the *lac* operon and ultimately synthesis of the enzyme β -galactosidase (encoded by *lacZ*). However, isopropylthiogalactoside (IPTG), a nonmetabolizable analog of allolactose that also induces the *lac* operon, is often used in the laboratory for detailed studies of lactose utilization and β -galactosidase activity in *E. coli*.

All regulatory systems employing repressors have the same underlying mechanism: prevention of mRNA synthesis by the activity of specific repressor proteins that are themselves under the control of specific small effector molecules. And, as previously noted, because the repressor's role is to stop transcription, regulation by repressors is called *negative control*. Another point to note is that genes are not turned on and off completely like light switches. DNA-binding proteins vary in concentration and affinity and thus control is quantitative. Even when a gene is “fully repressed” there is often a very low level of basal transcription.

Mechanisms of Activation

In contrast to repressor proteins binding and preventing transcription of DNA, some operons are transcribed only if a specific activator protein is first bound to the DNA (Figure 7.7). Activator protein binding is necessary in these cases because the promoter sequences in these operons are poor matches to consensus promoter sequences (◀ Section 6.5) and hence bind RNA polymerase only weakly. Thus, even with the correct sigma (σ) factor, the RNA polymerase has difficulty recognizing these promoters. And, in contrast to the case where operons are under repressor control (Figures 7.5 and 7.6), genes controlled

Figure 7.7 Activator protein interactions with RNA polymerase. (a) The activator-binding site is near the promoter. (b) The activator-binding site is several hundred base pairs from the promoter. In this case, the DNA must be looped to allow the activator and the RNA polymerase to interact.

by activator proteins are under *positive control* because the role of activator proteins is to facilitate rather than block transcription.

The function of activator proteins is to help the RNA polymerase recognize the promoter and begin transcription. For example, the activator protein may modify the structure of the DNA by bending it (Figure 7.8), allowing the RNA polymerase to make necessary contacts with nucleotides in the promoter region to begin transcription. Alternatively, the activator protein may interact directly with the RNA polymerase. This can happen either when the activator-binding site is close to the promoter (Figure 7.7a) or when it is several hundred base pairs away from the promoter, a situation in which DNA looping is required to make the necessary contacts between protein and nucleic acid (Figure 7.7b).

Figure 7.8 Computer model of a positive regulatory protein interacting with DNA. This model shows the cyclic AMP receptor protein (CRP), a regulatory protein that controls several operons. The α -carbon backbone of this protein is shown in blue and purple, while residues that bind cyclic AMP are shown in red. The protein is binding to a DNA double helix (shades of green). Note that binding of the CRP protein to DNA has bent the DNA.

An example of activation is the regulation of the maltose operon in *Escherichia coli*, which encodes the enzymes necessary for the catabolism of the disaccharide sugar maltose. This operon possesses a maltose activator protein called MalT that cannot bind to the DNA unless it first binds to its effector molecule, maltose (Figure 7.9). Thus, maltose is also considered an inducer molecule because the enzymes for maltose catabolism in *E. coli* are synthesized only after the addition of maltose to the medium. This follows the pattern shown for β -galactosidase in Figure 7.6c except that maltose rather than lactose is required to induce gene expression. When the maltose activator protein binds to DNA, it allows RNA polymerase to begin transcription (Figure 7.9b). Like repressor proteins, activator proteins bind specifically to particular sites within the DNA. However, the region on the DNA that is the binding site of the activator is not called an operator (Figures 7.5 and 7.6) but instead an *activator-binding site* (Figures 7.7 and 7.9). Nevertheless, the genes controlled by this activator-binding site are still called an operon.

Operons versus Regulons

In *E. coli*, the genes required for maltose utilization are spread out over the chromosome in several operons, each of which has an activator-binding site to which a copy of the maltose activator protein can bind (Figure 7.10). Therefore, the maltose activator protein actually controls the transcription of more than one operon. When more than one operon is under the control of a single regulatory protein, these operons are collectively called a **regulon**. Thus, the enzymes for maltose utilization are encoded by the maltose regulon. A set of operons whose promoters are recognized only by a specific alternative sigma (σ) factor (Table 6.3) is another example of a positively regulated regulon.

Regulons are known for operons under negative control or repression as well. For example, the arginine biosynthetic enzymes are

Figure 7.9 Positive control of enzyme induction in the maltose operon. (a) In the absence of an inducer, neither the MalT activator protein nor the RNA polymerase can bind to the DNA. (b) When the sugar maltose (the inducer of the *malEFG* operon) is present, it binds to the MalT activator protein, which in turn binds to the activator-binding site. This recruits RNA polymerase to bind to the *mal* promoter and begin transcription.

Figure 7.10 Maltose regulon of *Escherichia coli*. The genes and operons required for maltose utilization (*mal*) are dispersed throughout the *E. coli* genome and regulated by the same maltose regulatory protein (MalT). Note that the LacI repressor protein binds only to the *lac* operon, which is only located at one position on the chromosome, while the Mal repressor protein binds to multiple operons (the *mal* regulon).

encoded by the arginine regulon, whose operons are all under the control of the arginine repressor protein (only one of the arginine operons was shown in Figure 7.5). In regulon control, a specific DNA-binding protein binds only at those operons it controls regardless of whether it is functioning as an activator or repressor; other operons are not affected.

Many genes and regulons in *E. coli* have promoters under positive control and many have promoters under negative control. In addition, many operons have promoters with multiple types of control and some have more than one promoter, each with its own control system! Thus, the simple picture outlined above does not hold for all operons. Multiple control features are common in the operons and regulons of virtually all *Bacteria* and *Archaea*, and thus their overall regulation may require a network of interactions.

We now consider transcriptional control in *Archaea*, which has elements that both resemble and differ from those in *Bacteria*.

Check Your Understanding

- Compare and contrast the activities of an activator protein and a repressor protein.
- Distinguish between an operon and a regulon.

7.4 Transcription Controls in *Archaea*

As we have seen, there are two alternative approaches to regulating the activity of RNA polymerase. One strategy, common in *Bacteria*, is to use DNA-binding proteins that either block RNA polymerase activity (repressor proteins) or stimulate RNA polymerase activity

(activator proteins). An alternative strategy, common in eukaryotes, is to coordinate the binding of several proteins on the DNA to interact with RNA polymerase. Because these proteins affect the rate at which a gene is transcribed, they are also considered *transcription factors* (Section 7.2). Given the greater overall similarity between the mechanism of transcription in *Archaea* and *Eukarya* (◀ Section 6.6), it is perhaps surprising that the regulation of transcription in *Archaea* more closely resembles that of *Bacteria*.

Few repressor or activator proteins from *Archaea* have been characterized in the detail of the *arg*, *lac*, or *mal* operons of *Escherichia coli* (Figures 7.5, 7.6, 7.9, and 7.10), but it is clear that *Archaea* have both positive and negative control systems. Archaeal repressor proteins either block the binding of RNA polymerase itself or block the binding of TBP (TATA-binding protein) and TFB (transcription factor B), proteins that are required for RNA polymerase to bind to the promoter in *Archaea* (◀ Section 6.6). At least some archaeal activator proteins function in just the opposite way, by recruiting TBP to the promoter, thereby facilitating transcription.

Control of Nitrogen Assimilation in *Archaea*

A well-studied example of an archaeal repressor is the NrpR protein from the methanogen *Methanococcus maripaludis* (▶ Section 17.2). NrpR represses genes encoding nitrogen assimilation functions (Figure 7.11), such as those for nitrogen fixation (◀ Section 3.12) and

Figure 7.11 Repression of genes for nitrogen metabolism in *Archaea*. The NrpR protein of *Methanococcus maripaludis* functions as a repressor. It blocks the binding of the TFB and TBP proteins, which are required for promoter recognition, to the BRE (B recognition element) site and TATA box, respectively. If there is a shortage of ammonia, α-ketoglutarate is not converted to glutamate. The α-ketoglutarate accumulates and binds to NrpR, releasing it from the DNA and allowing TBP and TFB to bind. The latter promotes RNA polymerase binding and transcription of the operon.

synthesis of the amino acid glutamine. When organic nitrogen is plentiful in the *M. maripaludis* cell, NrpR represses nitrogen assimilation genes. However, if the level of organic nitrogen becomes limiting, the compound α -ketoglutarate accumulates to high levels. This occurs because α -ketoglutarate, a citric acid cycle intermediate, is also a major acceptor of ammonia during nitrogen assimilation (Section 3.14).

When levels of α -ketoglutarate rise, this signals the cell that ammonia is limiting and that additional pathways need to be activated for obtaining ammonia, such as nitrogen fixation or the activity of glutamine synthetase, the high-affinity nitrogen assimilation enzyme. Elevated levels of α -ketoglutarate function as an inducer by binding to the NrpR protein. In this state, NrpR loses its affinity for the promoter regions of its target genes and no longer blocks transcription from promoters. In this respect, the NrpR protein resembles the LacI repressor and similar-functioning proteins of *Bacteria* (Section 7.3 and Figure 7.6).

Dual-Acting Transcriptional Regulators in Archaea

Some archaeal regulators possess *dual functionality* and can function as both a repressor and an activator. For example, the TrmB family of transcriptional regulators that primarily regulate sugar metabolism is widespread in *Archaea*, with more than 250 proteins identified. The actual activity of the allosteric regulator depends on its DNA binding site. In *Pyrococcus furiosus*, a hyperthermophile that

does not possess a glucose transporter but can perform glycolysis, TrmBL1 simultaneously functions as a repressor of genes for other sugar transport systems present in this organism and as an activator of genes for glucose synthesis (gluconeogenesis, Section 3.13).

As a repressor, TrmBL1 binds to a specific DNA sequence *downstream* of the BRE (B recognition element)/TATA binding sites of maltodextrin and maltose/trehalose uptake genes (Figure 7.12a). This binding blocks the binding of RNA polymerase to these sites and thus prevents gene expression. If cellular conditions shift and the inducer sugars maltose, maltotriose, or fructose are present, they bind to TrmBL1, resulting in an allosteric change in the protein such that it can no longer bind DNA. Without TrmBL1 bound to the DNA, RNA polymerase is able to bind to the promoter region and derepression of sugar transporter genes occurs (Figure 7.12a).

In other metabolic situations, TrmBL1 can function as an activator protein by binding to a separate and distinct DNA sequence associated with genes for glucose biosynthesis. This regulatory region differs from the one that TrmBL1 binds to as a repressor as it is located *upstream* of the BRE/TATA binding sites (Figure 7.12b). Binding of TrmBL1 to this DNA sequence helps recruit the archaeal transcription initiation complex (TBP, TFB, and RNA polymerase, Section 6.6), thus activating transcription. However, in the same manner as its role as a repressor, TrmBL1 as an allosteric activator will not bind to DNA if the effector molecules maltose, maltotriose, or fructose are present. Without TrmBL1 binding upstream of the BRE/TATA

Figure 7.12 Dual functionality of the *Pyrococcus furiosus* TrmBL1 regulator. *Pyrococcus furiosus* is a hyperthermophilic species of the *Euryarchaeota* with a growth temperature optimum of 100°C (Section 17.4). (a) The TrmBL1 protein functions as a repressor of genes for sugar uptake. It binds to DNA downstream of the TATA box, blocking the binding of RNA polymerase.

Binding of maltose (or another inducer) to TrmBL1 results in release of the regulator from the DNA. Now RNA polymerase can bind and transcribe sugar uptake genes. (b) The TrmBL1 protein functions as an activator of genes for glucose synthesis. It binds to a sequence upstream of the promoter region and recruits the transcription initiation complex. This in

turn results in transcription of glucose synthesis genes. The presence of maltose results in release of TrmBL1 from the DNA. Without TrmBL1 bound to the DNA, TBP and TFB are not recruited and glucose synthesis genes are not transcribed. The DNA polymerase from *P. furiosus* is a valuable tool in biotechnology (Section 12.1).

sequences and activating transcription, RNA polymerase and the other needed initiation factors cannot be recruited for transcription of genes necessary for glucose synthesis. This dual-functioning control conserves energy by preventing expression of the gluconeogenesis pathway when other sugars that can be converted into glucose are present in the cell.

The SurR protein of *P. furiosus* is another example of a regulatory protein that functions as both an activator and a repressor, depending on the location of its binding site within the promoter region. SurR controls a catabolic shift of *P. furiosus* from fermentation (which produces H_2) to anaerobic respiration with sulfur (S^0) as electron acceptor, forming H_2S (◀ Section 3.10 and ▶ Section 14.12). When S^0 is *absent*, SurR binds to regulatory regions that activate transcription of genes that encode the enzyme hydrogenase such that *P. furiosus* can grow by fermentation. At the same time, SurR functions as a repressor to prevent transcription of genes encoding proteins that participate in sulfur metabolism. However, when S^0 is *present*, SurR no longer binds to DNA. Interestingly, this inability of SurR to bind is not the result of S^0 binding to SurR as an effector molecule but to the oxidation of cysteine residues within the DNA-binding domain of this regulatory protein that triggers its release from the DNA. This event both activates expression of genes that participate in S^0 metabolism and represses the synthesis of hydrogenase, needed for fermentative metabolism.

Many regulatory mechanisms are triggered by environmental stimuli, and we move on to explore some of the most common ones in Part II of the chapter.

Check Your Understanding

- What is the major difference between transcriptional regulation in *Archaea* and eukaryotes?
- How do transcriptional activators in *Archaea* often differ in mechanism from those in *Bacteria*?
- Explain how the *Pyrococcus furiosus* TrmBL1 transcription regulator is able to act as both an activator and a repressor.

II • Sensing and Signal Transduction

Microbial genomes encode an assortment of multilevel regulatory mechanisms that monitor the environment for changes signaling better (or worse) growth conditions and then trigger a response that best favors survival of the cell.

Prokaryotic cells regulate cell metabolism in response to many different environmental fluctuations, including changes in temperature, pH, oxygen or nutrient availability, and even to changes in the number of other cells present. To do this, cells receive signals from the environment and transmit them to the specific target to be regulated. Some of these signals are small molecules that enter the cell and function as effectors. However, in many cases the external signal is not transmitted directly to the regulatory protein but instead is detected by a cell surface sensing system that transmits the signal to the rest of the regulatory machinery, a process called **signal transduction**.

7.5 Two-Component Regulatory Systems

Because most signal transduction systems contain two parts, they are called **two-component regulatory systems**. Characteristically, such systems consist of a specific **sensor kinase protein**, usually located in the cytoplasmic membrane, and a **response regulator protein**, present in the cytoplasm.

A kinase is an enzyme that phosphorylates compounds, typically using phosphate from ATP. Sensor kinases detect a signal from the environment and phosphorylate themselves (a process called *auto-phosphorylation*) at a specific histidine residue on the protein (Figure 7.13). Sensor kinases thus belong to the class of enzymes called *histidine kinases*. The phosphate is then transferred from the sensor to another protein inside the cell, the response regulator. The latter is typically a DNA-binding protein that regulates transcription in either a positive or a negative fashion (Section 7.3). In the example shown in Figure 7.13, regulation is negative; the phosphorylated response regulator functions as a repressor that binds DNA, thereby blocking transcription. Once dephosphorylated, the response regulator is released and transcription is permitted.

For a balanced regulatory system to work properly, it must have a *feedback loop*, that is, a way to complete the regulatory circuit and terminate the response. This resets the system for another cycle. This feedback loop employs a *phosphatase*, an enzyme that removes the phosphate from the response regulator at a constant rate. The response regulator itself often catalyzes this reaction, although in

Figure 7.13 The control of gene expression by a two-component regulatory system. One component is a sensor kinase in the cytoplasmic membrane that phosphorylates itself in response to an environmental signal. The phosphoryl group is then transferred to the second component, a response regulator. The phosphorylated form of the response regulator then binds to DNA. In the system shown here, the phosphorylated response regulator is a repressor protein. The phosphatase activity of the response regulator slowly releases the phosphate from the response regulator and resets the system.

TABLE 7.1 Examples of two-component systems that regulate transcription in *Escherichia coli*

System	Environmental signal	Sensor kinase	Response regulator	Primary activity of response regulator ^a
Arc system	Oxygen	ArcB	ArcA	Repressor/activator
Nitrate and nitrite respiration (Nar)	Nitrate and nitrite	NarX NarQ	NarL NarP	Activator/repressor Activator/repressor
Nitrogen utilization (Ntr)	Shortage of organic nitrogen	NRII (=GlnL)	NRI (=GlnG)	Activator of promoters requiring RpoN/ σ^{54}
Pho regulon	Inorganic phosphate	PhoR	PhoB	Activator/repressor
Porin regulation	Osmotic pressure	EnvZ	OmpR	Activator/repressor

^aNote that many response regulator proteins act as both activators and repressors depending on the genes being regulated. Although ArcA can function as either an activator or a repressor, it functions as a repressor on most operons that it regulates.

some cases separate proteins are needed (Figure 7.13). Phosphatase activity is typically slower than kinase (phosphorylation) activity. However, if phosphorylation ceases due to reduced sensor kinase activity, phosphatase activity eventually returns the response regulator to the fully nonphosphorylated state, and the system is reset.

Examples of Two-Component Regulatory Systems

Two-component systems regulate a large number of genes in many different *Bacteria*, and some key examples include those that respond to phosphate limitation, nitrogen limitation, and osmotic pressure; we focus on the latter two systems here.

In *Escherichia coli* almost 50 different two-component systems are present, and several are listed in Table 7.1. In one example, the osmolarity (dissolved solute concentration) of the environment controls the relative levels of the proteins OmpC and OmpF in the *E. coli* outer membrane. OmpC and OmpF are *porins*, proteins that allow metabolites to cross the outer membrane of gram-negative bacteria (◀ Section 2.4). If osmotic pressure is *low*, the synthesis of OmpF, a porin with a larger pore, increases; if osmotic pressure is *high*, OmpC, a porin with a smaller pore, is made in larger amounts.

EnvZ, a sensor histidine kinase in the *E. coli* cytoplasmic membrane, detects changes in osmotic pressure. When a shift occurs, EnvZ is autophosphorylated and transfers its phosphate group to OmpR, the response regulator of this system (Figure 7.14a). Under conditions of *low* osmotic pressure, phosphorylated OmpR (OmpR-P) *activates* transcription of the *ompF* gene. Conversely, when osmotic pressure is *high*, OmpR-P *represses* transcription of *ompF* and simultaneously activates transcription of *ompC* (Figure 7.14a). The expression of *ompF* is also regulated by an additional control mechanism—regulatory RNA—and we consider this additional level of regulation in Section 7.12.

Some signal transduction systems have a secondary regulatory element that is *not* RNA-based, and their activities can quickly become quite complex. Such is the case with the regulation of nitrogen assimilation in *Bacteria*. For instance, in the Ntr regulatory system (Figure 7.14b), the response regulator is an activator protein called *nitrogen regulator I* (NRI). In the phosphorylated state, NRI-P oligomerizes and binds to an activator-binding site over 100 base pairs upstream of the promoter region for nitrogen assimilation genes (Figure 7.14b). This binding causes the DNA to loop around such that NRI-P can make contact with RNA polymerase and the alternative sigma factor σ^{54} (RpoN) (◀ Section 6.5); this activates

transcription of genes that encode key nitrogen assimilation enzymes (Figure 7.7b). Phosphorylation of NRI is controlled by the sensor kinase of the Ntr system called *nitrogen regulator II* (NRII), which senses ammonia levels in the cell. However, NRII can switch from *kinase* activity to *phosphatase* activity depending on the nitrogen status of the cell (Figure 7.14b).

The dual enzymatic activity of NRII is controlled by the state of another protein called *PII*, a signal-transducing protein we will visit later when we consider regulation of an important ammonia assimilation protein, glutamine synthetase (Section 7.16). Under nitrogen starvation conditions, a nucleotide called uridine monophosphate (UMP) is added to PII, forming PII-UMP (Section 7.16). If PII-UMP is present in the cell, it stimulates the kinase activity of NRII. Thus the presence of PII-UMP leads to NRI-P and activation of genes encoding enzymes of nitrogen assimilation (Figure 7.14b). Conversely, if nitrogen is present in excess in the cell, UMP is removed from PII. PII in its unmodified form promotes the phosphatase activity of NRII, which results in unphosphorylated NRI. Without phosphorylation of NRI, transcriptional activation of nitrogen assimilation genes does not occur (Figure 7.14b). This type of regulation in which a hierarchy of control systems are deployed in a cascading fashion is common for systems of central importance to cellular metabolism.

Although rare in *Archaea*, two-component systems closely related to those in *Bacteria* are also present in microbial eukaryotes, such as the yeast *Saccharomyces cerevisiae*, and even in plants. However, most eukaryotic signal transduction pathways are distinct systems that phosphorylate serine, threonine, or tyrosine residues of proteins and are unrelated to those of the bacterial two-component systems that phosphorylate histidine residues (Figures 7.13 and 7.14a).

Check Your Understanding

- What are kinases and what is their role in two-component regulatory systems?
- What are phosphatases and what is their role in two-component regulatory systems?

7.6 Regulation of Chemotaxis

We have previously seen that some motile cells of *Bacteria* and *Archaea* respond to challenges such as nutrient limitation and toxin accumulation by moving toward attractants and away from

Figure 7.14 Two examples of well-studied two-component systems in *Escherichia coli*. (a) Regulation of synthesis of outer membrane proteins. The cytoplasmic membrane histidine kinase EnvZ autophosphorylates itself under osmotic pressure changes and then activates the transcriptional regulator OmpR by phosphorylation. OmpR-P binds upstream of the *ompF* gene and activates transcription under low osmotic pressure; conversely, it represses transcription of *ompF* under high osmotic pressure. OmpR-P only activates transcription of the *ompC* gene under conditions of high osmolarity. (b) Regulation of ammonia assimilation by the Ntr system. NRII is the sensor kinase and NRI is the response regulator. Genes encoding nitrogen assimilation proteins are only transcribed when cellular levels of ammonia are low.

repellents, a behavior called *chemotaxis* (◀ Section 2.11). We noted there that prokaryotic cells are too small to sense spatial gradients of a chemical, but they can respond to temporal gradients. That is, they can sense the *change* in concentration of a chemical over time rather than the absolute concentration of the chemical stimulus. Chemotactic activity of the opportunistic pathogen *Pseudomonas aeruginosa* scavenging nutrients from damaged epithelial cells is shown visually in **Figure 7.15**.

Chemotaxis has been well studied in *Bacteria*, which use a modified two-component regulatory system (Section 7.5) to sense temporal changes in attractants or repellents and process this information to regulate the direction of flagellar rotation. This differs from what was considered in the previous section in that the two-component system is used to regulate the activity of *preexisting proteins* (the flagellum protein complex) rather than to control the transcription of genes encoding flagellar proteins.

Response to Signal

The mechanism of chemotaxis depends upon a signal cascade of multiple proteins. Sensory proteins sense attractants or repellents and interact with cytoplasmic sensor kinases. These sensory proteins

are called *methyl-accepting chemotaxis proteins* (MCPs). MCPs allow the cell to monitor the concentration of various substances over time. Thousands of MCPs cluster to form large hexagonal arrays of proteins known as chemoreceptors. Depending on the microbe, these chemoreceptors can be located in the cytoplasmic membrane and/or cytoplasm. *Vibrio* species, which are often associated with coastal marine waters, contain both transmembrane and cytoplasmic chemoreceptors for sensing (**Figure 7.16**), whereas *Escherichia coli* only contains transmembrane chemoreceptors.

E. coli possesses four transmembrane chemoreceptors, each composed of five different MCPs that are specific for certain compounds. For example, the Tar MCP of *E. coli* senses the attractants aspartate and maltose and the repellents cobalt and nickel. MCPs bind attractants or repellents directly or in some cases indirectly through interactions with periplasmic binding proteins (◀ Sections 2.2 and 2.4), which allows for a wider range of signals to be sensed.

MCP binding of an attractant or repellent triggers interactions with the cytoplasmic proteins CheA and CheW (**Figure 7.17**). CheA is the sensor kinase (Section 7.5) for chemotaxis. When MCPs bind to an attractant *or* release a repellent, CheW is inactive and phosphorylation of CheA is inhibited (**Figure 7.17a**). Thus, an increase

Figure 7.15 Chemotaxis of *Pseudomonas aeruginosa* cells toward nutrients from damaged epithelial cells. A time series of fluorescence micrographs illustrating epithelial cells (blue: alive; red: dead) and *P. aeruginosa* (green) pre- and post-epithelial cell wounding. (a) Before damage of the epithelial layer by scratching. (b) Two minutes after scratching the epithelial monolayer, very few bacterial cells are present. (c) Five minutes after wound induction, *P. aeruginosa* cells migrate to the damaged epithelial cells to devour nutrients released from the cells. (d) After 30 minutes, some of the epithelial cells die (red) and the bacterial hunters move on to scavenge more nutrients from living cells. Images adapted from Schwarzer, C., Fisher, H., and Machen, T.E. 2016. *PLoS ONE* 11(3): e0150109.

in attractant *decreases* the rate of CheA autophosphorylation and the response regulator CheY remains unphosphorylated. When an MCP binds a repellent *or* releases an attractant, it changes conformation and, with help from CheW, leads to the autophosphorylation of CheA to form CheA-P (Figure 7.17b). Thus, an increase in repellent concentration *increases* the rate of CheA autophosphorylation. CheA-P then transfers the phosphate to CheY (forming CheY-P); this is the response regulator (Section 7.5) that controls flagellar rotation. As described in the next subsection, CheY-P leads to clockwise flagellar rotation. CheA-P can also transfer the phosphate to a different protein, CheB, which plays a role in adaptation (Figure 7.17), to be detailed shortly.

Controlling Flagellar Rotation

CheY is a central protein in the regulatory system because it governs the direction of rotation of the flagellum. Recall that if rotation of the flagellum is counterclockwise, *Escherichia coli* will continue to move in a run (swim smoothly), whereas if the flagellum rotates clockwise, the cell will tumble (move randomly) (◀ Section 2.11

Figure 7.16 *Vibrio* chemoreceptor arrays. Electron tomograph of a cell of *Vibrio cholerae* showing membrane-bound and cytoplasmic chemoreceptor arrays.

and Figure 2.33). When MCPs bind a repellent or release an attractant, CheY is phosphorylated. CheY-P interacts with the flagellar motor to induce clockwise flagellar rotation, which causes tumbling (Figure 7.17b). When MCPs bind an attractant or release a repellent, CheY is unphosphorylated and cannot bind to the flagellar motor. This results in the flagellum rotating counterclockwise, causing the cell to run (Figure 7.17a). Another protein, CheZ, dephosphorylates CheY, returning it to the form that allows runs instead of tumbles. Thus an increase in repellent concentration leads to an increase in the level of CheY-P and therefore tumbling. By contrast, if the cell is swimming toward attractants, the lower level of CheY-P suppresses tumbles and promotes runs.

Adaptation

Once an organism has successfully responded to a stimulus, it must stop responding and reset the sensory system to await further signals. This is known as *adaptation*. During adaptation of the chemotaxis system, a feedback loop resets the system. This relies on the response regulator CheB, mentioned earlier.

As their name implies, MCPs can be methylated. When MCPs are fully methylated they no longer respond to attractants but are sensitive to repellents. Conversely, when MCPs are unmethylated they respond strongly to attractants but are insensitive to repellents. Varying the methylation level thus allows adaptation to sensory signals. This is accomplished by methylation and demethylation of the MCPs. CheR is the chemotaxis protein that methylates MCPs, while phosphorylated CheB (CheB-P) is the protein that demethylates MCPs (Figure 7.17). Note that CheA-P donates a phosphate group not only to CheY as described above, but to CheB as well (Figure 7.17b).

If the level of an attractant remains high, the rate of CheA autophosphorylation is low. This leads to unphosphorylated CheY and CheB (Figure 7.17). Consequently, the cell swims smoothly in a run. Methylation of the MCPs increases during this period because CheB-P is not present to demethylate them. However, MCPs no longer respond to the attractant when they become fully methylated.

Figure 7.17 Mechanism of chemotaxis in *Escherichia coli*. Methyl-accepting chemotaxis proteins (MCPs) within chemoreceptor arrays form a complex with the sensor kinase CheA and the coupling protein CheW. (a) Binding of an attractant to MCP (or an empty MCP) inhibits CheA kinase activity. Without phosphorylation of CheY, the flagellar switch continues in a

counterclockwise (CCW) rotation and cell running toward the attractant occurs. (b) Binding of a repellent to MCP stimulates CheA, which can then phosphorylate the response regulators CheB and CheY. Binding of phosphorylated CheY (CheY-P) to the flagellar motor switch results in clockwise (CW) rotation and cell tumbling. CheZ is responsible for dephosphorylating CheY-P

so that the response can continue or cease depending on the activity of CheA. CheR continually adds methyl groups to the MCP, while CheB-P (but not CheB) removes them. The degree of methylation of the MCPs controls their ability to respond to attractants and repellents and leads to adaptation.

Therefore, if the level of attractant remains high but constant, the cell begins to tumble. Eventually, CheB becomes phosphorylated and CheB-P demethylates the MCPs. This resets the receptors, allowing them to once again respond to further increases or decreases in the level of attractants. Put another way, the cell stops swimming if the attractant concentration is constant. It only continues to swim if ever higher levels of attractant are encountered. The course of events is just the opposite for repellents. Fully methylated MCPs respond best to an increasing gradient of repellents and send a signal for cell tumbling to begin. The cell then moves off in a random direction while MCPs are slowly demethylated. With this mechanism for adaptation, chemotaxis successfully achieves the ability to monitor small changes in the concentrations of both attractants and repellents over time.

Other Taxes

In addition to chemotaxis, several other forms of taxis are known, for example, *phototaxis* (movement toward light) and *aerotaxis* (movement toward oxygen) (◀ Section 2.12). Interestingly, many of the cytoplasmic Che proteins that function to control flagellar activity in chemotaxis also play a role in these other taxes. For example, in phototaxis, a light sensor protein replaces the MCPs of chemotaxis, and in aerotaxis, a redox protein monitors levels of oxygen. These sensors then interact with cytoplasmic Che proteins to begin the cascade of events that direct runs or tumbles. Thus several different kinds of environmental signals converge on the same flagellar control system, and this allows the cell to economize on its regulatory systems.

Check Your Understanding

- What are the primary response regulator and the primary sensor kinase for regulating chemotaxis?
- Why is adaptation during chemotaxis important?
- How does the response of the chemotaxis system to an attractant differ from its response to a repellent?

7.7 Cell-to-Cell Signaling

Populations of *Bacteria* and *Archaea* are able to communicate with one another through the production of small extracellular molecules. Depending on the cell, these molecules can be either small peptides or nonpeptide organic molecules. Accumulation of these signaling molecules often leads to coordinated group behaviors such as biofilm formation (◀ Section 4.9 and ▶ Section 8.10), and because accumulation is essential, the density of cells producing specific signaling molecules in a local environment ultimately controls such pathways. This regulatory phenomenon is called **quorum sensing** (the word “quorum” in this sense meaning “sufficient numbers”).

Mechanism of Quorum Sensing

Quorum sensing is a regulatory mechanism that assesses population density. Many bacteria use this approach to ensure that sufficient cell numbers of their own species are present before initiating activities that require a certain cell density to work effectively. For

Figure 7.18 Quorum sensing. (a) A cell capable of quorum sensing expresses acyl homoserine lactone (AHL) synthase at basal levels. This enzyme makes the cell's specific AHL. When cells of the same species reach a certain density, the concentration of AHL rises sufficiently to bind to the activator protein, which activates transcription of quorum-specific genes. (b) General structure of an AHL. Different AHLs are variants of this parent structure. R = alkyl group (C₁–C₁₇); the carbon next to the R group is often modified to a keto group (C=O).

example, a pathogenic bacterium that secretes a toxin will have no effect as a single cell; production of toxin by one cell alone would merely waste the cell's resources. However, if a sufficiently large population of cells is present, the coordinated expression of the toxin may successfully cause disease and release resources from the host that can be used to support growth of the pathogen.

Quorum sensing is widespread among gram-negative *Bacteria* but is also found in many gram-positive species and in some *Archaea*. Each species that employs quorum sensing produces a specific signal molecule called an **autoinducer** (Figure 7.18). This molecule typically diffuses freely across the cell envelope in either direction. Because of this, the autoinducer reaches high concentrations inside the cell only if many cells are nearby, each making the same autoinducer. In the cytoplasm, the autoinducer binds to a specific transcriptional activator protein or a sensor kinase of a two-component system (Sections 7.3–7.5), ultimately triggering transcription of specific genes (Figure 7.18a).

While several different classes of autoinducers exist, the first to be identified were the *acyl homoserine lactones* (AHLs) (Figure 7.18b). Several different AHLs, with acyl groups (functional groups containing both carbonyl and alkyl groups) of different lengths, are found in different species of gram-negative bacteria. In addition, many gram-negative *Bacteria* make autoinducers such as AI-2 (a cyclic furan derivative) that can be used between many different species, thus allowing more widespread gram-negative interspecies communication. Gram-positive *Bacteria* and some *Archaea* generally use certain small peptides as autoinducers.

The phenomenon of quorum sensing was discovered as the mechanism by which light emission in bioluminescent bacteria is regulated (► Sections 16.4 and 23.10). Several bacterial species can emit light, including the marine bacterium *Aliivibrio fischeri*. Figure 7.19 shows bioluminescent colonies of *A. fischeri*. The light is generated by an enzyme called *luciferase*. The *lux* operons encode the proteins needed for bioluminescence and are under control of the activator protein LuxR. The *lux* operons are induced when the concentration of the specific *A. fischeri* AHL, *N*-3-oxohexanoyl homoserine lactone, becomes high enough. When this occurs, LuxR binds to the *lux* operons and activates their transcription.

Quorum sensing has also been observed in microbial eukaryotes. For example, in the yeast *Saccharomyces cerevisiae*, specific aromatic alcohols are produced as autoinducers and control the transition between growth of *S. cerevisiae* as single cells and as elongated filaments. Similar transitions are seen in other dimorphic fungi (fungi capable of two different morphologies), some of which cause disease in humans. An example is *Candida*, whose quorum sensing is mediated by the long-chain alcohol farnesol. As the concentration of farnesol increases, the transition from budding yeast cells to elongated hyphae is prevented.

Virulence Factors

Various genes are controlled by quorum sensing, including some in pathogenic bacteria. For example, Shiga toxin-producing *Escherichia coli*, such as the notorious foodborne pathogen *E. coli* O157:H7 (► Section 33.11), produces an AHL called AI-3 that induces virulence genes. As the *E. coli* population increases in the intestine, bacterial cells produce AI-3 while host intestinal cells produce the stress hormones epinephrine and norepinephrine. All three of these signal molecules bind to two separate sensor kinases in the *E. coli* cytoplasmic membrane, resulting in the phosphorylation and activation of two transcriptional activator proteins (Figure 7.20a). These proteins

Timothy C. Johnston

(a) Virulence factor production in Shiga toxin-producing *Escherichia coli*

Figure 7.20 Quorum sensing regulation of virulence factors in two common bacterial pathogens. *Escherichia coli* and *Staphylococcus aureus* can be harmless saprophytes or potent pathogens, depending on the strain. As pathogens, the production of major virulence factors is controlled by quorum sensing. (a) As the bacterial population increases, AI-3 produced by *Escherichia coli* and epinephrine and norepinephrine

produced by the intestinal cell accumulate and bind to sensor kinases, initiating a cascade of events necessary for production of virulence factors (for example, enterotoxin). (b) Basal level transcription of the *argABCD* operon in *Staphylococcus* leads to production of ArgD, the pre-autoinducing peptide (AIP). ArgB trims ArgD into the functional AIP and exports it out of the cell. As the cell population increases, the AIP

(b) Virulence factor production in *Staphylococcus aureus*

concentration increases and binds to ArgC, leading to autophosphorylation of ArgC. ArgC-P then activates the transcriptional activator ArgA by transfer of a phosphate group. ArgA-P increases transcription of the *argABCD* operon as well as activating the transcription of an RNA that leads to the production of virulence proteins.

activate transcription of genes encoding motility functions and secretion of the toxin as well as genes encoding proteins that form lesions on the host intestinal mucosa, thus releasing nutrients that can be used by cells of the pathogen. This is a rare example of a system that senses both bacterial and eukaryotic chemical signals to regulate gene expression.

The pathogenesis of the gram-positive bacterium *Staphylococcus aureus* (► Section 31.9) requires, among many other things, the production and secretion of small extracellular peptides that damage host cells or that interfere with the host's immune system. The genes encoding these virulence factors are under the control of a quorum-sensing system that uses a small peptide called the *autoinducing peptide* (AIP), encoded by the *argD* gene, as the autoinducer. After synthesis of ArgD (pre-AIP), the membrane-bound ArgB protein trims the peptide into its active AIP form and secretes the small peptide outside of the cell (Figure 7.20b). As the cell density of *S. aureus* increases, so does the concentration of AIP. ArgC is a membrane-bound sensor kinase (Section 7.5) that binds to AIP, resulting in autophosphorylation. ArgC-P then transfers its phosphate to the transcriptional activator ArgA. ArgA-P increases transcription of *argABCD* genes that encode the signal transduction system as well as an RNA molecule that controls production of a range of virulence proteins.

Some eukaryotes produce molecules that specifically interfere with bacterial quorum sensing. Most of these found so far have been furanone derivatives containing a halogen atom. These components mimic the AHLs or AI-2 and disrupt bacterial behavior that relies on quorum sensing. Because of this, quorum-sensing disruptors have

been proposed as potential drugs to disperse bacterial biofilms (◀ Section 4.9 and ► Section 8.10) and prevent the expression of virulence genes.

In the next part we explore mechanisms of controlling large gene sets scattered across the chromosome, something the cell must do to coordinate the expression of genes not linked in a single operon.

Check Your Understanding

- What advantage do quorum-sensing systems confer on bacterial cells?
- What properties are required for a molecule to function as an autoinducer?
- How do the autoinducers used in quorum sensing by gram-negative bacteria differ from those used by gram-positive bacteria?

III • Global Control

Some microbial regulatory systems control the expression of several sets of genes scattered across the genome in order to activate or repress the synthesis of groups of functionally related proteins in a single control event.

An organism often needs to regulate many unrelated genes simultaneously in response to a change in its environment. Regulatory mechanisms that respond to environmental signals by

TABLE 7.2 Examples of global control systems known in *Escherichia coli*^a

System	Signal	Primary activity of regulatory protein	Number of genes regulated
Aerobic respiration	Presence of O ₂	Repressor (ArcA)	> 50
Anaerobic respiration	Lack of O ₂	Activator (FNR)	> 70
Catabolite repression	Cyclic AMP level	Activator (CRP)	> 300
Heat shock	Temperature	Alternative sigma factors (RpoH and RpoE)	> 36
Nitrogen utilization	NH ₃ limitation	Activator (NRI)/alternative sigma factor (RpoN)	> 12
Oxidative stress	Oxidizing agents	Activator (OxyR)	> 30
SOS response	Damaged DNA	Repressor (LexA)	> 20
General stress response	Stress conditions	Alternative sigma factor (RpoS)	> 400

^aFor many of the global control systems, regulation is complex. A single regulatory protein can play more than one role. For instance, the regulatory protein for aerobic respiration is a repressor for many promoters but an activator for others, whereas the regulatory protein for anaerobic respiration is an activator protein for many promoters but a repressor for others. Regulation can also be indirect or require more than one regulatory protein. Many genes are regulated by more than one global system.

regulating the transcription of many different genes comprising more than one regulon are called *global control systems*. There are several global control systems in *Escherichia coli* (and probably in all *Bacteria* and *Archaea*), and some key ones are listed in **Table 7.2**. Global control networks may include activators, repressors, signal molecules, two-component regulatory systems, regulatory RNA (Section 7.12), and alternative sigma (σ) factors (◀ Section 6.5) as components of the overall control system.

7.8 The *lac* Operon

Both the lactose operon and the maltose regulon respond to global controls in addition to their own controls discussed in Section 7.3. We begin our consideration of global regulation by revisiting the *lac* operon and considering how cells respond when more than one sugar is available.

Catabolite Repression

In its intestinal habitat, *Escherichia coli* likely encounters several different utilizable carbon sources, and for this reason, the organism is genetically equipped to catabolize many different sugars. When given several sugars, including glucose, do cells of *E. coli* use them simultaneously or one at a time? The answer is that *glucose is always used first*. It would be wasteful to induce enzymes for using other sugars when glucose is available because *E. coli* grows faster on glucose than on any other carbon source. **Catabolite repression** is a mechanism of global control that controls the use of carbon sources if more than one is present.

When cells of *E. coli* are grown in a medium that contains glucose, the synthesis of enzymes needed for the breakdown of other carbon sources (such as lactose or maltose) is repressed, even if those other carbon sources are present. Thus, the presence of a favored carbon source represses the induction of pathways that catabolize other carbon sources. Catabolite repression is sometimes called the “glucose effect” because glucose was the first substance shown to cause this response. But catabolite repression is not always linked to glucose; the key point is that the favored substrate is a better carbon and energy source than other available carbon and energy sources.

Why is catabolite repression called *global* control? In *E. coli* and other organisms for which glucose is the best energy source, catabolite repression prevents expression of most other catabolic operons

as long as glucose is present. Dozens of catabolic operons are affected, including those for lactose (Figure 7.6), maltose (Figure 7.9), a host of other sugars, and most other commonly used carbon and energy sources for *E. coli*. In addition, genes for the synthesis of flagella are controlled by catabolite repression because if bacteria have a good carbon source available, there is no need to swim around in search of nutrients.

One consequence of catabolite repression is that it may lead to two exponential growth phases, a phenomenon called *diauxic growth*. If two usable energy sources are available, the cells first consume the better energy source. Growth stops when the better source is depleted, but following a lag period, it resumes on the other energy source. Diauxic growth is illustrated in **Figure 7.21** for a culture of *E. coli* grown on a mixture of glucose and lactose. The cells grow more rapidly on glucose than on lactose. Although glucose and lactose are both excellent energy sources for *E. coli*, glucose is superior and supports a higher growth rate.

The proteins of the *lac* operon, including the enzyme β -galactosidase, are required for using lactose and are induced in its presence (Figure 7.6). But the synthesis of these proteins is subject to catabolite

Figure 7.21 Diauxic growth of *Escherichia coli* on a mixture of glucose and lactose. The presence of glucose represses the synthesis of β -galactosidase, the enzyme that cleaves lactose into glucose and galactose. After glucose is depleted, there is a lag during which β -galactosidase is synthesized. Growth then resumes on lactose but at a slower rate, as indicated by the green line.

repression, and as long as glucose is present, the *lac* operon is not expressed and lactose is not used. However, when glucose is depleted, catabolite repression is abolished and the *lac* operon is expressed; shortly thereafter, cells begin to grow on lactose. How are all of these events controlled?

Cyclic AMP and Cyclic AMP Receptor Protein

Despite its name, catabolite repression relies on an activator protein and is actually a form of activation (Section 7.3). The activator protein is called the *cyclic AMP receptor protein* (CRP). A gene that encodes a catabolite-repressible enzyme is expressed only if CRP binds to DNA in the promoter region. This allows RNA polymerase to bind to the promoter. CRP is an allosteric protein and binds to DNA only if it has first bound a small molecule called *cyclic adenosine monophosphate* (cyclic AMP or *cAMP*), a derivative of the nucleotide adenosine present in RNA (Figure 7.22). Like many DNA-binding proteins (Section 7.1), CRP binds to DNA as a dimer.

Cyclic AMP is a key molecule in many metabolic control systems, both in prokaryotic cells and eukaryotes. Because it is derived from a nucleic acid precursor, it is a **regulatory nucleotide**. Other regulatory nucleotides include cyclic guanosine monophosphate (cyclic GMP; important mostly in eukaryotes), cyclic di-GMP (important in biofilm formation; ◀ Section 4.9 and ▶ Section 8.10), and guanosine tetraphosphate (ppGpp, important in the stringent response, Section 7.9). Cyclic AMP is synthesized from ATP by an enzyme called *adenylate cyclase* (Figure 7.22). However, glucose inhibits the synthesis of cyclic AMP and also stimulates cyclic AMP transport out of the cell. When glucose enters the cell, the cyclic AMP level is lowered, CRP cannot bind DNA, and RNA polymerase fails to bind to the promoters of operons subject to catabolite repression. Thus, catabolite repression is an *indirect* result of the presence of a better energy source (glucose); the *direct* cause of catabolite repression is a low level of cyclic AMP.

Figure 7.22 Cyclic AMP. Cyclic adenosine monophosphate (cyclic AMP) is made from ATP by the enzyme adenylate cyclase.

Figure 7.23 Overall regulation of the *lac* system. The *lac* operon consists of *lacZ*, encoding β -galactosidase, *lacY*, encoding lactose permease, and *lacA*, encoding lactose acetylase. The LacI repressor protein is encoded by a separate gene, *lacI*. LacI binds to the operator (O) unless the inducer is present. The cyclic AMP receptor protein (CRP) binds to the CRP activator site (C) when activated by cyclic AMP and recruits RNA polymerase to bind to the promoter (P). For the *lac* operon to be transcribed by RNA polymerase, the LacI repressor must be absent (that is, inducer must be present) and cyclic AMP levels must be high (due to the absence of glucose), allowing CRP to bind.

Let us return to the *lac* operon and include catabolite repression. The entire regulatory region of the *lac* operon is diagrammed in Figure 7.23. For *lac* genes to be transcribed, two requirements must be met: (1) The level of cyclic AMP must be high enough for the CRP protein to bind to the CRP-binding site (positive control), and (2) lactose or another suitable inducer must be present so that the lactose repressor (LacI protein) does not block transcription by binding to the operator (negative control). If these two conditions are met, the cell is signaled that glucose is absent and lactose is present; then and only then does transcription of the *lac* operon begin.

We now consider another form of global control distinct from catabolite repression but where regulatory nucleotides play a central role.

Check Your Understanding

- Explain how catabolite repression depends on an activator protein.
- What role does cyclic AMP play in glucose regulation?
- Explain how the *lac* operon is both positively and negatively controlled.

7.9 Stringent and General Stress Responses

In nature microorganisms must often survive nutrient-limited conditions and exposure to environmental stressors such as extreme pH, oxidative stress, and antibiotic exposure. How do cells cope and adapt to such conditions? While some gram-positive bacteria undergo sporulation to withstand such harsh conditions (◀ Section 2.8), many *Bacteria* instead activate a variety of *stress survival pathways*—including both specific and general—that improve their chances of survival.

Mechanism of the Stringent Response

The **stringent response** is a widely distributed regulatory mechanism used by bacteria to survive nutrient deprivation, environmental stresses, and antibiotic exposure. Triggering of the stringent response ultimately leads to a shutdown of macromolecule synthesis and the activation of pathways to improve the cell's ability to survive and compete in nature.

Nutrient levels for microbes in nature can change significantly and rapidly. Such changing conditions can easily be simulated in the laboratory, and much work has been done on the regulation of

gene expression following a “shift down” or “shift up” in nutrient status. These include, in particular, the regulatory events triggered by starvation for amino acids or energy, experiments that led to the discovery of the stringent response.

As a result of a shift down from amino acid excess to limitation, as occurs when a culture is transferred from a rich complex medium to a defined medium with a single carbon source (◀ Table 4.2), the synthesis of rRNA and tRNA ceases almost immediately, and no new ribosomes are produced (Figure 7.24a). Protein and DNA synthesis are also curtailed, but the biosynthesis of new amino acids is activated. Following such a shift, new proteins must be made to synthesize the amino acids no longer available in the environment, and these proteins are made by existing ribosomes. After a while, rRNA synthesis (and hence, the production of new ribosomes) begins again but at a new rate commensurate with the cell's reduced growth rate (Figure 7.24a). This course of events is called the *stringent response* (or stringent control) and, like catabolite repression (Section 7.8), is another example of global control.

The stringent response is triggered by a mixture of two regulatory nucleotides, *guanosine tetraphosphate* (ppGpp, Figure 7.24b) and

(a)

(c)

(b)

(d)

Figure 7.24 The stringent response in *Escherichia coli*. (a) Upon nutrient downshift, rRNA, tRNA, and protein syntheses temporarily cease. Sometime later, growth resumes at a decreased rate. (b) Structure of guanosine tetraphosphate (ppGpp), a trigger of the stringent response. (c) Normal translation, which requires charged tRNAs. (d) Synthesis of ppGpp. When cells are starved for amino acids, an uncharged tRNA can bind to the ribosome, which stops ribosome activity. This event triggers the RelA protein to synthesize a mixture of pppGpp and ppGpp.

guanosine pentaphosphate (pppGpp) [collectively, these are referred to as (p)ppGpp]. In *Escherichia coli*, these nucleotides, which are also called *alarmones*, rapidly accumulate during stress or a shift down from amino acid excess to amino acid starvation. Alarmones are synthesized by a specific protein, called RelA, using ATP as a phosphate donor (Figure 7.24c, d). RelA adds two phosphate groups from ATP to GTP or GDP, thus producing pppGpp or ppGpp, respectively. RelA is associated with the 50S subunit of the ribosome and is activated by a signal from the ribosome during amino acid limitation. When the growth of the cell is limited by a shortage of amino acids, the pool of *uncharged* tRNAs increases relative to *charged* tRNAs (◀ Section 6.8). Eventually, an uncharged tRNA is inserted into the ribosome instead of a charged tRNA during protein synthesis. When this happens, the ribosome stalls, and this leads to (p)ppGpp synthesis by RelA (Figure 7.24d). The protein Gpp converts pppGpp to ppGpp so that ppGpp is the major overall product.

The alarmones ppGpp and pppGpp have global control effects. They strongly inhibit rRNA and tRNA synthesis by binding to RNA polymerase and preventing initiation of transcription of genes for these RNAs in gram-negative bacteria. In gram-positive bacteria, the same alarmones have been shown to interfere with initiating ribonucleotides for transcription. In both gram-negative and gram-positive *Bacteria*, the alarmones activate both the stress response pathways and the biosynthetic operons for certain amino acids. In *E. coli*, the stringent response also inhibits the initiation of new rounds of DNA synthesis and cell division and slows down the synthesis of cell envelope components, such as membrane lipids.

In addition to RelA, a second protein called SpoT helps trigger the stringent response. SpoT can either make (p)ppGpp or degrade it. Under most conditions, SpoT is responsible for degrading (p)ppGpp; however, SpoT synthesizes (p)ppGpp in response to certain stresses or when nutrient (and thus energy) deprivation is detected. Thus the stringent response results not only from the absence of precursors for protein synthesis, but also from the lack of energy for biosynthesis.

The Stringent Response and Microbial Ecology

Because the stringent response is a global mechanism that balances the metabolic state of the cell, the environment or habitat of the bacterium ultimately determines the response cascade. When cells of *E. coli* are voided in the feces and face a switch from the nutrient-rich intestine to an open water system, the reduction in nutrients triggers ppGpp synthesis to initiate the stringent response (Figure 7.25a).

In contrast to *E. coli*, the aquatic bacterium *Caulobacter* naturally inhabits oligotrophic (nutrient-poor) freshwaters, and in this bacterium, the stringent response is triggered by carbon and ammonia starvation, not amino acid limitation. *Caulobacter* can form two types of cells, stalked cells and swarmer cells (Figure 7.25b). To increase its probability of survival, the production of ppGpp in *Caulobacter* leads to an increase in swarmer cell formation. Unlike stalked cells, swarmer cells are motile and can therefore swim and perhaps reach a niche containing more nutrients (▶ Section 8.8; Figure 7.25b).

In a disease example, the stringent response has also been implicated in the persistence of the aerobic bacterial pathogen

Figure 7.25 Environmental control of stringent response signaling in *Escherichia coli* and *Caulobacter crescentus* (both gram-negative bacteria), and *Mycobacterium tuberculosis* (a gram-positive bacterium). (a) *Escherichia coli*. When *E. coli* cells move from the nutrient-rich intestine to an open water source, they experience nutrient limitation. As ppGpp production increases, cell division is inhibited. (b) *Caulobacter crescentus*. *C. crescentus* naturally inhabits freshwater systems that are limited in nutrients. If cells encounter severe nutrient limitation, the stringent response is induced and ppGpp production increases. This increase leads to the cell morphology changing from stalked cells to swarmer cells that can swim to find more nutrients. (c) *Mycobacterium tuberculosis*. When *M. tuberculosis* cells enter a host, the bacterial cells are exposed to the host's immune response. This leads to production of ppGpp, which converts some cells to relatively dormant persister cells. These persister cells are resistant to antibiotics and can dominate more sensitive vegetative cells, forming granulomas. Once persister cells are aerosolized and relieved of stress, they revert back to infective vegetative cells. Unlike many other bacterial pathogens that acquire antibiotic resistance from mobile genetic elements, horizontal gene transfer is rare in *M. tuberculosis*. Antibiotic resistance in this pathogen is primarily due to chromosomal mutations affecting the target of the antibiotic.

Mycobacterium tuberculosis (tuberculosis, ► Section 31.4) in dormant granulomas. Within the lung of the human tuberculosis patient, the local environment is both hypoxic (low in O_2) and limited for phosphate, and these conditions trigger the stringent response in cells of *M. tuberculosis*. Activation of the stringent response also leads to a subpopulation of *M. tuberculosis* cells that convert to dormant *persistor cells* (► Section 8.12); these cells are resistant to antibiotics and can survive in granulomas that form in the lung (Figure 7.25c). Once drug treatment of the infection has greatly reduced cell numbers and the environmental stresses have been relieved, the *M. tuberculosis* *persistor cells* can then revert back to infective cells and trigger chronic tuberculosis, a not uncommon occurrence and one of the reasons drug therapy for tuberculosis is carried out over a long period.

The General Stress Response: The RpoS Regulon

Bacterial cells often respond to nutrient limitation and stressors by entering into the stationary phase of growth (◄ Section 4.6). This growth switch is controlled by activating a regulon recognized by the alternative sigma factor RpoS (σ^S or σ^{38} , ◄ Table 6.3), also called the *stationary phase sigma factor*. The RpoS regulon comprises over 400 genes including those associated with nutrient limitation, resistance to DNA damage, biofilm formation, and responses to osmotic, oxidative, and acid stresses. Thus, RpoS not only senses environmental changes but also relays signals to other regulators.

Examples of *E. coli* genes that are recognized by RpoS include *dinB*, which encodes DNA polymerase IV of the SOS DNA repair system (► Section 9.4 and Figure 9.10) and catalase genes necessary for combating reactive oxygen species (◄ Section 4.16). Because of the expansive nature of the RpoS regulon, this alternative sigma factor is itself controlled by several transcriptional, translational, and post-translational regulatory mechanisms. For example, transcription of the *rpoS* gene increases in response to the presence of the alarmone ppGpp, thus directly linking the RpoS regulon with the stringent response. Translation of *rpoS* mRNA is also positively regulated by the presence of small RNAs expressed during stress conditions (Section 7.12). Conversely, the RpoS protein is susceptible to degradation during nonstressful conditions. Overall, the general stress response highlights the global control nature of RpoS and the coordinated processes that a cell must undertake for adaptation and survival in nature.

We next consider a more specific global regulatory mechanism focused on phosphate, an essential nutrient for life (◄ Section 4.1).

Check Your Understanding

- Which *Escherichia coli* genes are activated and which are repressed during the stringent response, and why?
- How are the alarmones ppGpp and pppGpp synthesized?
- What are some other conditions that trigger the stringent response in other bacteria?

7.10 The Phosphate (Pho) Regulon

Phosphorus is not only essential for DNA, RNA, and membrane synthesis, but it is also critical for energy generation (◄ Section 4.1) and cell signaling. In nature, phosphorus is generally in the form of

inorganic phosphate (PO_4^{3-} , abbreviated P_i) and is often the limiting nutrient in many environments. Because of this, P_i transformations are heavily regulated. The *phosphate (Pho)* regulon consists of a two-component regulatory system (Section 7.5) that responds to P_i limitation. This global control system includes not only genes encoding extracellular enzymes for extracting P_i from organic phosphates, but also genes encoding P_i transporters, enzymes for P_i storage, and other energy-requiring metabolic and biosynthesis pathways as well.

Streptomyces and Phosphate

Streptomyces is a genus of gram-positive *Bacteria* that contains many species that produce antibiotics (► Section 16.12) and whose phosphate metabolism has been well studied. While antibiotic production is an energy-intensive process, the process is limited by high phosphate concentrations. In the environment, *Streptomyces* produce antibiotics to kill competing cells. Thus, low phosphate levels signal *Streptomyces* that competition for resources is keen, and this results in antibiotic production.

In *Streptomyces*, the two-component Pho regulatory system that senses P_i limitation consists of a membrane-bound histidine kinase sensor protein PhoR and a cytoplasmic transcriptional regulator PhoP. While the mechanism for actually *sensing* extracellular P_i levels is unknown, low environmental P_i levels trigger PhoR kinase activity, yielding a phosphorylated PhoP (PhoP-P) (Figure 7.26). Once phosphorylated, PhoP-P binds to conserved promoter regions called “Pho boxes” scattered across the genome. This binding

Figure 7.26 The phosphate (Pho) regulon of *Streptomyces*. If inorganic phosphate (P_i) concentrations are low, the kinase PhoR is signaled to phosphorylate PhoP. PhoP-P recognizes and binds to several promoters, functioning as either an activator or a repressor. This regulation results in activating phosphate uptake and antibiotic synthesis genes and decreasing nitrogen metabolism by repressing genes regulating glutamine synthetase (*glnA*) and ammonium transport (*amtB*), respectively.

signals the major sigma subunit of *Streptomyces* RNA polymerase to bind, and *activates* transcription of genes needed for P_i uptake. The same event occurs with promoters for some genes that encode products necessary for antibiotic production. By contrast, when P_i is present in excess, PhoP is dephosphorylated, and this leads to the removal of PhoP from Pho boxes and a decreased transcription of genes encoding proteins of phosphate metabolism and antibiotic synthesis.

While the Pho regulon is the mechanism many *Bacteria* use to respond to P_i starvation, why is this regulon considered an example of *global* control? Besides its role as an activator of P_i uptake and antibiotic synthesis genes in *Streptomyces* and of P_i genes in many other *Bacteria*, PhoP-P also binds some promoters weakly without recruiting a sigma subunit. This binding blocks RNA polymerase and thus leads to repression of the linked gene. Somewhat surprisingly, PhoP-P appears to actually repress more genes than it activates. Genes regulated by P_i limitation and PhoP-P that are unassociated with P_i uptake in *Streptomyces* include those whose products are necessary for nitrogen metabolism (glutamine synthetase, *glnA*; ammonium transport, *amtB*) (Figure 7.26). The physiological rationale here is that if P_i levels are growth limiting, the cell's production of key biosynthetic intermediates (such as amino acids) should be reduced until P_i levels increase.

Pathogenesis and the Pho Regulon

The Pho regulon can also control some aspects of pathogenesis. Pathogenic bacteria are exposed to both P_i -limiting and P_i -rich environments within a host depending on the site of infection. The genome of Shiga toxin-producing *Escherichia coli*, such as the notorious foodborne pathogen *E. coli* O157:H7 (► Section 33.11), contains a Pho regulon of over 40 genes. In its normal habitat—the intestinal tract—*E. coli* often experiences phosphate limitation, and this condition activates the cytoplasmic-membrane-bound PhoR. This protein then transfers a phosphate group to the cytoplasmic transcriptional regulator and DNA-binding protein PhoB (the equivalent to the *Streptomyces* PhoP, Figure 7.26). PhoB-P triggers increased expression not only of the genes for phosphate metabolism, but also of genes encoding the acid shock protein Asr and Shiga toxin. Increased production of Asr leads to protection of periplasmic proteins from acid stress, which would be encountered by *E. coli* cells present in the stomach en route to the intestine. Once the pathogen is inside an intestinal cell, its Shiga toxin production is responsible for the severe diarrhea associated with the infection, an event that effectively transmits the pathogen to a new host. Thus, phosphate limitation leads to increased fitness and survivability of pathogenic strains of *E. coli*.

While the mechanisms remain unclear, the Pho regulon has also been implicated in regulating biofilm formation (◄ Section 4.9 and ► Section 8.10), antimicrobial resistance (► Section 28.7), and toxin production (► Section 25.6) in other pathogenic bacteria such as *Vibrio cholerae* and *Pseudomonas* species. Thus, although the Pho regulon is the major barometer of P_i starvation, its activities impact a wide range of unrelated genes that control several distinct cellular functions.

We move on now to the last section of Part III to consider globally regulated systems found in all domains of life that respond to major temperature shifts, the phenomenon of heat shock.

Check Your Understanding

- What category of regulatory system is the Pho regulon?
- What types of bacterial processes are activated and repressed by phosphate limitation?

7.11 The Heat Shock Response

Most proteins are relatively stable, even to small increases in temperature. However, some proteins are less stable at elevated temperatures and tend to unfold (denature, ◄ Section 6.7). Other stress conditions besides heat can lead to protein denaturation. These include exposure to high levels of certain solvents (for example, ethanol), osmotic stress, and high doses of ultraviolet (UV) light. Because protein stability is critical for survival, cells employ a global control mechanism called the **heat shock response** to protect cells from protein denaturation. This response features many of the regulatory modes illustrated in Figure 7.1.

Heat Shock Proteins

Temperature and various stress conditions can generate large amounts of inactive proteins that need to be either refolded (and in the process, reactivated) or degraded to release free amino acids for the synthesis of new proteins (enzymes called *proteases* facilitate the latter process). Consequently, heat stress and other conditions that lead to protein unfolding trigger the synthesis of a set of proteins known as **heat shock proteins**. Heat shock proteins help counteract protein damage and assist the cell in recovering from stress.

In most *Bacteria* and *Archaea* there are five major classes of heat shock protein: Hsp100, Hsp90, Hsp70, Hsp60, and Hsp10. We have encountered some of these proteins before, although not by these names (◄ Section 6.11 and Figure 6.40a). The Hsp70 protein of *Escherichia coli* is DnaK, which prevents aggregation of newly synthesized proteins and stabilizes unfolded proteins. Major representatives of the Hsp60 and Hsp10 families in *E. coli* are the proteins GroEL and GroES, respectively. These are *molecular chaperones* that catalyze the correct refolding of misfolded proteins. Another group of heat shock proteins (Hsp100) includes various proteases that degrade denatured or irreversibly aggregated proteins. Because heat shock proteins perform vital functions in the cell, a low level of these proteins is always present, even under optimal conditions. However, genes encoding many bacterial heat shock proteins also make up a regulon (Section 7.3) whose expression is increased by the presence of an alternative sigma factor known as *RpoH*.

The Alternative Sigma Factor RpoH

In many bacteria, such as *E. coli*, the heat shock response is controlled by the alternative RNA polymerase σ factor (◄ Section 6.5) RpoH (σ^{32}) (Figure 7.27). RpoH controls expression of heat shock proteins and is normally degraded within a minute or two of its synthesis. However, when cells suffer a heat shock (or other stressor that leads to protein denaturation), degradation of RpoH is inhibited and its level therefore increases. As a consequence, transcription of those operons whose promoters are recognized by RpoH increases.

The rate of RpoH degradation depends on the level of free DnaK, which inactivates RpoH. In unstressed cells, the level of free DnaK

Figure 7.27 Control of heat shock in *Escherichia coli*. (a) The mRNA that encodes the alternative sigma factor RpoH folds under normal conditions, thus blocking the ribosome-binding site (RBS) and limiting translation. The RpoH protein that is made is broken down rapidly by proteases at 32°C, and binding of the DnaK chaperone to RpoH stimulates this degradation. (b) At 40°C, the mRNA encoding RpoH unfolds and more RpoH protein is made. The shift in temperature also denatures some proteins and DnaK recognizes, binds, and refolds these unfolded polypeptide chains. This removes RpoH from DnaK, which slows the degradation rate of RpoH. When the level of RpoH rises, the heat shock genes are transcribed.

is relatively high and the level of intact RpoH is correspondingly low (Figure 7.27a). However, if heat begins to unfold proteins, DnaK binds preferentially to unfolded proteins and so is no longer free to degrade RpoH (Figure 7.27b). Thus, the more denatured proteins there are, the lower the level of free DnaK and the higher the level of RpoH; the result is heat shock gene expression. When the environmental stressor has passed, for example upon a temperature downshift, RpoH is once again inactivated by DnaK and the synthesis of heat shock proteins is reduced. Thus, DnaK functions as a cellular “thermometer” for the heat shock response and its inactivation of RpoH is considered a form of post-translational regulation, which we will discuss in Section 7.16.

Not only is the activity of the RpoH protein controlled, but translation of its corresponding mRNA is also regulated. Under normal cellular conditions, the *rpoH* mRNA base-pairs within itself (Figure 7.27a). This folding results in a secondary structure that decreases the ribosome’s ability to bind to the ribosome-binding site (RBS) of the mRNA (◀ Section 6.9). However, when the cell’s internal temperature increases, the mRNA encoding RpoH unfolds. This unfolding allows the ribosome easier access and thus more overall RpoH protein production under the heat shock response (Figure 7.27b).

There is also a heat shock response in *Archaea*, even in species that grow optimally at very high temperatures. An analog of the bacterial Hsp70 is found in many *Archaea* and is structurally similar to that present in gram-positive species of *Bacteria*. However, other types of heat shock proteins unrelated to the stress proteins of *Bacteria* are

also present in *Archaea*. Moreover, a heat shock response also exists in eukaryotes. Thus, this critically important mechanism for salvaging damaged yet recoverable proteins is present in all domains of life.

Check Your Understanding

- What is the heat shock response?
- How do levels of RpoH control the heat shock response?
- How is translation of the *rpoH* mRNA controlled?

IV • RNA-Based Regulation

In the course of evolution, prokaryotic cells have missed out on few if any potential regulatory mechanisms. For example, controls employing RNAs (rather than proteins) to monitor the cell’s status and trigger specific gene expression are known and are widespread in *Bacteria* and *Archaea*.

Thus far we have focused on regulatory mechanisms in which proteins sense signals or bind to DNA. In some cases, a single protein does both; in other cases, separate proteins carry out these two activities. Nonetheless, all of these mechanisms rely on regulatory *proteins*. However, some regulatory mechanisms employ *RNA* to regulate gene expression, both at the level of transcription and at the level of translation, and we consider these now.

7.12 Regulatory RNAs

RNA molecules that are not translated to give proteins are collectively known as **noncoding RNA (ncRNA)**. This category includes the rRNAs and tRNAs that participate in protein synthesis and the RNA present in the signal recognition particle that catalyzes some types of protein secretion (◀ Sections 6.8, 6.10, and 6.12). Noncoding RNA also includes small RNA molecules necessary for RNA processing, especially the splicing of mRNA in eukaryotes (◀ Section 6.6). *Small RNAs* (sRNAs) that range from 40 to 400 nucleotides long and regulate gene expression are widely distributed in both prokaryotic cells and eukaryotes. In *Escherichia coli*, for example, a number of sRNA molecules regulate several aspects of cell physiology in response to environmental or cellular signals by binding to other RNAs or in some cases to other small molecules; the end result is control of gene expression.

Small RNAs (sRNAs) exert their effects by base-pairing directly to other RNA molecules, usually mRNAs, in regions of complementary sequence. This binding immediately modulates the rate of target mRNA translation because a ribosome cannot translate double-stranded RNA. Thus, sRNAs provide an additional mechanism to regulate the synthesis of a protein once its corresponding mRNA has already been made.

Mechanisms of sRNA Activity

Small RNAs alter the translation of their mRNA target by four different mechanisms (Figure 7.28). Some sRNAs base-pair to their target mRNA, changing its secondary structure to either block a previously accessible ribosome-binding site (RBS) (◀ Section 6.9) or to open up a previously blocked RBS, allowing access for the ribosome. These two events decrease or increase expression of the protein encoded by the target mRNA, respectively. The other two

mechanisms of sRNA interaction affect mRNA stability; binding of the sRNA to its target either increases or decreases degradation of the transcript by bacterial ribonucleases, thus modulating protein expression. Increased degradation of an mRNA prevents the synthesis of new protein molecules encoded by that mRNA. Alternatively, increasing the stability of mRNA will lead to higher corresponding protein levels in the cell (Figure 7.28).

Types of Small RNA

Small RNAs are important modulators of various cellular processes including oxidative, iron limitation, and glucose–phosphate stresses as well as quorum sensing, biofilm formation, and stationary phase events. Transcription of sRNAs is often enhanced under conditions in which their target genes need to be silenced. For example, the RyhB RNA of *Escherichia coli* is transcribed when iron is limiting for growth. RyhB sRNA binds to several distinct target mRNAs that encode proteins needed for iron metabolism or that use iron as cofactors. Binding of RyhB sRNA blocks the RBS of the mRNA and thus inhibits translation (Figure 7.28a). The base-paired RyhB/mRNA molecules are then degraded by ribonucleases, in particular, ribonuclease E, before translation of the mRNA can occur. Small RNA control forms only part of the mechanism by which *E. coli* and related bacteria reduce the production of iron-requiring proteins in response to iron limitation. Other responses include transcriptional controls by repressor and activator proteins (Section 7.2) that decrease or increase, respectively, the capacity of cells to take up iron or to tap into intracellular iron reserves.

Similarly, SgrS is an sRNA in *E. coli* that is expressed during glucose–phosphate stress to avoid accumulation of glucose 6-phosphate. High levels of glucose 6-phosphate within the cell can block the glycolytic pathway (◀ Section 3.6) and ultimately lead to

Figure 7.28 Small RNA mechanisms for modulating the translation of mRNA. (a) Binding of a ribosome to mRNA requires that the ribosome-binding site (RBS) of the mRNA be single-stranded. Binding of an sRNA to the RBS (shown in 1) can prevent translation while the binding of an sRNA to an mRNA whose RBS has secondary structure (shown in 2) can stimulate translation. (b) Ribonuclease degrades RNA. Ribonuclease binding to partially double-stranded RNA results in RNA degradation (shown in 1), while sRNA binding at the ribonuclease binding site (shown in 2) can protect the mRNA from degradation. Compare the mechanisms for controlling translation by small RNAs shown in this figure with the mechanism of controlling translation by a riboswitch shown in Figure 7.31a.

Figure 7.29 The interaction of SgrS sRNA and *ptsG* mRNA during glucose–phosphate stress. Three-dimensional super-resolution image of fluorescently labeled SgrS sRNA (red) and *ptsG* mRNA (green) in cells of *Escherichia coli*. (a) Before glucose–phosphate stress at time 0, *ptsG* mRNA is more abundant than SgrS sRNA. (b) After 10 min of glucose–phosphate stress, SgrS levels are higher, which leads to degradation of *ptsG* mRNA.

cell death if not overcome. When SgrS is expressed, the sRNA molecule binds to the *ptsG* mRNA encoding a glucose transporter. This binding results in a double-stranded RNA complex that triggers degradation of *ptsG* mRNA by ribonuclease E, as shown in living cells in **Figure 7.29**. This degradation decreases the amount of *ptsG* mRNA that is translated, and thus lower levels of the glucose transporter protein are made. This in turn results in decreased cellular levels of glucose 6-phosphate (recall that glucose is transported into *E. coli* by the phosphotransferase system, which converts glucose into glucose 6-phosphate during the transport process, ◀ Section 2.2 and Figure 2.6). By reducing glucose 6-phosphate levels, the glycolytic pathway remains active.

Because many sRNAs, including RyhB and SgrS, are encoded in intergenic regions and can be spatially separated from their mRNA target, they are called *trans*-sRNAs. As such, these sRNAs usually have limited complementarity to their target molecule and may only base-pair with a 5- to 11-nucleotide stretch. The binding of *trans*-sRNAs to their targets often depends on a small protein called Hfq (**Figure 7.30**) that binds to both mRNA and its corresponding sRNA to facilitate their interaction. Hfq forms hexameric rings with

Figure 7.30 The RNA chaperone Hfq holds RNAs together. Binding of sRNA to mRNA often requires assistance from the Hfq protein. Small RNA molecules usually have several stem–loop structures. One consequence is that the complementary base sequence that recognizes the mRNA is noncontiguous.

RNA-binding sites on both surfaces. Hfq and functionally similar proteins are called *RNA chaperones*, as they help small RNA molecules, including many sRNAs, maintain their correct structure (**Figure 7.30**).

Small RNAs do not always work by affecting mRNA. For example, replication of the ColE1 plasmid in *Escherichia coli* is regulated by an sRNA that primes DNA synthesis on the plasmid and its antisense partner that blocks initiation of DNA synthesis. The level of the antisense RNA determines how often replication is initiated. Some sRNAs also bind directly to proteins and modulate their activity. Thus, depending on the sRNA, these molecules can affect several different activities in the cell.

In the next section we examine a different form of RNA-based regulation from that we have considered here with the sRNAs.

Check Your Understanding

- How do sRNAs alter the translation of target mRNAs?
- Why do *trans*-sRNAs often require a chaperone protein?
- How does SgrS help *Escherichia coli* prevent a potential metabolic disaster?

7.13 Riboswitches

RNA can carry out many roles once thought to be limited to proteins. In particular, RNA can specifically recognize and bind other molecules, including low-molecular-weight metabolites. It is important to emphasize that such binding does not require complementary base pairing (as does binding of the sRNAs described in the previous section) but results from the folding of the RNA into a specific three-dimensional structure that recognizes the target molecule, much as a protein enzyme recognizes its substrate in its active site. Catalytically active RNAs are called *ribozymes*. Other RNA molecules resemble repressors and activators in binding small metabolites and regulating gene expression; these are the **riboswitches**, our focus here.

Mechanisms of Riboswitches

Earlier in this chapter we discussed the regulation of gene expression by negative control of transcription (Section 7.3). In this process, a specific metabolite interacts with a specific repressor protein to prevent transcription of genes encoding enzymes for the biosynthetic pathway of the metabolite. In contrast, in a riboswitch there is no regulatory protein. Instead, the metabolite binds directly to a specific mRNA. This binding results in the riboswitch controlling gene expression at either the transcriptional or translational level, depending on the type of riboswitch.

Riboswitch RNAs have sequences upstream of their coding regions (5'-UTR; **Figure 7.1**) that can fold into specific three-dimensional structures that bind small molecules. These recognition domains are the *aptamer region* or “switch” in the riboswitch and exist as two alternative secondary structures, one with the small molecule bound and the other without (**Figure 7.31**). Alternation between the two forms of the riboswitch thus depends on the presence or absence of the small molecule, which in turn controls the secondary structure of the downstream RNA called the *expression platform* of the riboswitch. In one type of riboswitch, the secondary structure of the expression platform controls whether the ribosome binds to the

Figure 7.31 Regulation by a riboswitch. Riboswitches are located in the 5' untranslated region (UTR) of mRNAs (Figure 7.1). The aptamer region of the riboswitch binds specifically to the metabolite. Numbers indicate regions within the riboswitch expression platform that can base-pair together, and RBS indicates the ribosome-binding site. (a) Translational regulation: Binding of a specific metabolite alters the secondary structure of the riboswitch domain, preventing translation. (b) Transcriptional regulation: Binding of a specific metabolite alters the secondary structure of the riboswitch domain, which results in the formation of a transcriptional terminator, preventing transcription of the coding region of the gene. Compare this process to that of attenuation shown in Figure 7.33a.

corresponding mRNA's ribosome-binding site (RBS) and begins translation (Figure 7.31a); in another type, it controls whether RNA polymerase continues to transcribe the mRNA (Figure 7.31b). Riboswitches exist in all three domains of life, with over 40 different types known in *Bacteria*. Riboswitches control not only the synthesis of enzymes in biosynthetic pathways for various vitamins, a few amino acids, some nitrogen bases of nucleic acids, and a peptidoglycan precursor, but also aspects related to biofilm formation, fluoride toxicity, and molybdenum/tungsten cofactor metabolism (Table 7.3). The metabolite that is bound by the riboswitch aptamer region is typically the product of a biosynthetic pathway whose constituent enzymes are encoded by the mRNAs that carry the corresponding riboswitches. For example, the thiamine riboswitch that binds the vitamin thiamine pyrophosphate lies upstream of the coding sequences for enzymes that participate in the thiamine biosynthetic pathway. When the pool of thiamine pyrophosphate is sufficient in the cell, this metabolite binds to the aptamer region of its specific riboswitch mRNA. This binding results in a secondary structure of the riboswitch that blocks the ribosome-binding site on the mRNA; this prevents translation (Figure 7.31a). If the concentration of thiamine pyrophosphate drops sufficiently low, the molecule dissociates

from its riboswitch mRNA, and this unfolds the mRNA and exposes the ribosome-binding site, allowing the mRNA to bind to the ribosome and be translated. In contrast to riboswitches that control *translation*, some riboswitches control *transcription*. This mechanism is similar to

TABLE 7.3 Riboswitches in biosynthetic pathways of <i>Escherichia coli</i>	
Type	Example of biosynthetic pathway
Vitamins	Cobalamin (B ₁₂), tetrahydrofolate (folic acid), thiamine
Amino acids	Glutamine, glycine, lysine, methionine
Nitrogen bases of nucleic acids	Adenine, guanine (purine bases)
Others	Flavin mononucleotide (FMN), S-adenosylmethionine (SAM), glucosamine 6-phosphate (peptidoglycan precursor), cyclic di-GMP (biofilm signaling molecule), molybdenum cofactor (Moco), fluoride resistance proteins

regulation by attenuation, to be discussed in Section 7.14. With transcriptional riboswitches, metabolite binding to the aptamer region results in a conformational change within the expression platform that causes RNA polymerase to prematurely terminate synthesis of the mRNA (Figure 7.31*b*). This occurs because metabolite binding converts the expression platform to a form that mimics a traditional transcriptional terminator (◀ Section 6.5). The SAM (S-adenosylmethionine) riboswitch associated with sulfur metabolism in gram-positive bacteria such as *Bacillus* is a good example of a riboswitch that controls transcription in this way. SAM is a cofactor in the methionine biosynthesis pathway and its availability is a signal that sufficient methionine levels exist in the cell. Binding of SAM to the SAM riboswitch aptamer forms a transcriptional terminator in the downstream expression platform, and this results in decreased levels of mRNAs encoding methionine biosynthesis enzymes and enzymes in other sulfur metabolism pathways that require SAM.

Conversely, some riboswitches that control transcription employ the opposite form of control—binding of the metabolite *removes* the stem-loop structure that terminates transcription. When this occurs, increased levels of the mature mRNA are eventually formed and, following translation, yield increased levels of the protein(s) it encodes.

Riboswitches and Evolution

How widespread are riboswitches and how did they evolve? Thus far riboswitches have been found only in some *Bacteria*, *Archaea*, and a few plants and fungi. Some scientists believe that riboswitches are remnants of the RNA world, a period eons ago before cells, DNA, and protein were present when it is hypothesized that catalytic RNAs were the only self-replicating “life forms” (▶ Section 13.1 and Figure 13.4). In such an environment, riboswitches may have been an early mechanism of metabolic control—a simple means by which RNA life forms could have controlled the synthesis of other RNAs. As proteins evolved and DNA became the genetic material of all cells, riboswitches might have been the first control mechanisms for RNA (and even protein) synthesis as well. If this is true, the riboswitches that we see today may be the last vestiges of this simple form of control because, as we have seen in this chapter, metabolic regulatory mechanisms in cells are almost exclusively carried out by regulatory *proteins*.

We end this part of our study of microbial control with the description in the next section of one additional mechanism, a fascinating process by which cells essentially “decide” on whether to complete translation of a protein even before transcription of the mRNA that encodes it has been completed.

Check Your Understanding

- What happens when a riboswitch binds the small metabolite that regulates it?
- What are the major differences between a repressor protein and a riboswitch in the control of gene expression?

7.14 Attenuation

Attenuation is a form of transcriptional control in *Bacteria* and *Archaea* that functions by prematurely terminating mRNA synthesis. That is, in attenuation, control is exerted *after* the initiation of

transcription but *before* its completion. Consequently, the number of *completed* transcripts from an operon is reduced, even though the number of *initiated* transcripts is not.

The basic principle of attenuation is that the first part of the mRNA to be made, called the *leader*, can fold into two alternative secondary structures. In this respect, the mechanism of attenuation resembles that of riboswitches that terminate transcription (Figure 7.31*b*). In attenuation, one mRNA secondary structure allows continued synthesis of the mRNA, whereas the other secondary structure causes premature termination. Folding of the mRNA depends either on events at the ribosome or on the activity of regulatory proteins, depending on the organism. The best examples of attenuation are the regulation of genes controlling the biosynthesis of certain amino acids in gram-negative *Bacteria*. The first to be described was in the tryptophan operon in *Escherichia coli*, and we focus on it here. Unlike the situation in prokaryotic cells, the processes of transcription and translation are spatially separated in eukaryotes (◀ Section 6.6), and thus attenuation control is absent from *Eukarya*.

Attenuation in the Tryptophan Operon

The tryptophan operon contains structural genes for five proteins of the tryptophan biosynthetic pathway plus the usual promoter and regulatory sequences at the beginning of the operon (Figure 7.32). Like many operons, the tryptophan operon has more than one type of regulation. Transcription of the entire tryptophan operon is controlled by a repressor protein and its corepressor (tryptophan; Section 7.3). However, in addition to the promoter and operator regions needed for negative control, there is a

Figure 7.32 Attenuation and leader peptides in *Escherichia coli*. Structure of the tryptophan (*trp*) operon and of the tryptophan leader peptide and other leader peptides in *E. coli*. (a) Arrangement of the *trp* operon. Note that the leader (L) encodes a short peptide containing two tryptophan residues near its terminus (there is a stop codon following the Ser codon). The promoter is labeled P, and the operator is labeled O. The genes labeled *trpE* through *trpA* encode the enzymes needed for tryptophan synthesis. (b) Amino acid sequences of leader peptides of some other amino acid biosynthesis operons. Because isoleucine is made from threonine, it is an important constituent of the threonine leader peptide.

sequence in the operon called the *leader sequence* that encodes a short polypeptide—the *leader peptide*—that functions as a translational barometer. The leader sequence contains tandem tryptophan codons near its terminus and is the “attenuator” of the attenuation system (Figure 7.32).

The basis of control of the tryptophan attenuator is as follows. If tryptophan is plentiful in the cell, there will be plenty of charged tryptophan tRNAs and the leader peptide will be synthesized. Synthesis of the leader peptide results in termination of transcription of the remainder of the *trp* operon, which includes the structural genes for the biosynthetic enzymes. By contrast, if tryptophan is scarce, the tryptophan-rich leader peptide will not be synthesized. If synthesis of the leader peptide is arrested by a shortage of tryptophan, the rest of the operon is transcribed.

Mechanism of Attenuation

How does translation of the leader peptide regulate transcription of the tryptophan genes downstream? Consider that in prokaryotic cells transcription and translation are simultaneous processes; as mRNA is released from the DNA, the ribosome binds to it and translation begins (◀ Section 6.1 and Figure 6.6). That is, while *transcription* of downstream DNA sequences is still proceeding, *translation* of transcribed sequences is already under way (Figure 7.33).

Transcription is attenuated because a portion of the newly formed mRNA folds into a unique stem-loop that inhibits RNA polymerase activity. The stem-loop structure forms in the mRNA because two stretches of nucleotides near each other are complementary and can thus base-pair. If tryptophan is plentiful, the ribosome translates the leader sequence until it comes to the leader stop codon. The remainder of the leader sequence then forms a stem-loop, a transcription pause site, which is followed by a uracil-rich sequence that actually triggers termination (Figure 7.33a).

If the concentration of tryptophan in the cell is limiting, transcription of genes encoding tryptophan biosynthetic enzymes is needed. Thus, during transcription of the leader, the ribosome pauses at a tryptophan codon because of a shortage of charged tryptophan tRNAs. The presence of the stalled ribosome at this position allows a stem-loop to form (sites 2 and 3 in Figure 7.33b) that differs from the terminator stem-loop. This alternative stem-loop is not a transcription termination signal but instead prevents the terminator stem-loop (sites 3 and 4 in Figure 7.33a) from forming. This allows RNA polymerase to move past the termination site and begin transcription of tryptophan structural genes. Thus, in attenuation, we see a situation in which the rate of *transcription* is ultimately influenced by the rate of *translation*, a situation that contrasts with typical cellular events where the rate of translation is controlled by the rate of transcription.

We finish up this chapter on regulation by examining in Part V two major mechanisms that cells have evolved to control the activities of proteins they have already made.

Check Your Understanding

- Why does attenuation control not occur in eukaryotes?
- Explain how the formation of one stem-loop in the RNA can block the formation of another.

Figure 7.33 Mechanism of attenuation. Control of transcription of the *Escherichia coli* tryptophan (*trp*) operon structural genes by attenuation. The leader peptide is encoded by regions 1 and 2 of the mRNA. Two regions of the growing mRNA chain are able to form double-stranded loops, labeled as 3:4 and 2:3. (a) When there is excess tryptophan, the ribosome translates the complete leader peptide, and so region 2 cannot pair with region 3. Regions 3 and 4 then pair to form a loop that terminates transcription. (b) If translation is stalled because of tryptophan starvation, a loop forms by pairing of region 2 with region 3, loop 3:4 does not form, and transcription proceeds past the leader sequence.

V • Regulation of Enzymes and Other Proteins

Once a protein is made, its activity may still be subject to control. This ensures that cellular metabolites are synthesized in a balanced fashion and that energy is not expended making metabolites already present in excess of biosynthetic needs.

We have just explored some of the key mechanisms for regulating the *amount* (or even the complete presence or absence) of an enzyme or other protein within a cell. Here we focus on the

mechanisms that cells employ to control the *activity* of enzymes already present in the cell through processes such as feedback inhibition and post-translational regulation.

7.15 Feedback Inhibition

A major means of controlling enzymatic activity is by **feedback inhibition**. This mechanism temporarily shuts off the reactions in an entire biosynthetic pathway. The reactions are shut off because an excess of the end product of the pathway inhibits activity of an early (typically the *first*) enzyme of the pathway. Inhibiting an early step effectively shuts down the entire pathway because no intermediates are generated for subsequent enzymes in the pathway (Figure 7.34a). Feedback inhibition is reversible, however, because once levels of the end product become limiting, the pathway again becomes functional.

How can the end product of a pathway inhibit the activity of an enzyme whose substrate is quite unrelated to it? This occurs because the inhibited enzyme has two binding sites, the *active site* (where substrate binds, ◀ Section 3.5), and the *allosteric site*, where the end product of the pathway binds. When the end product is in excess, it binds at the allosteric site, changing the conformation of the enzyme such that the substrate can no longer bind at the active site (Figure 7.34b). When the concentration of the end product in the cell begins to fall, however, the end product no longer binds to the allosteric site, so the enzyme returns to its catalytic form and once again becomes active.

Some biosynthetic pathways controlled by feedback inhibition employ *isoenzymes* (“iso” means “same”). Isoenzymes are different proteins that catalyze the same reaction but are subject to different regulators, such as those required for the synthesis of the aromatic amino acids tyrosine, tryptophan, and phenylalanine in *Escherichia*

coli, a branched biosynthetic pathway (Figure 7.34c). Three isoenzymes catalyze formation of DAHP, an early intermediate of the pathway, and each is regulated independently by a different end product amino acid. In this way, synthesis of DAHP is inhibited *incrementally*, an excess of all three amino acids being necessary to completely shut down the pathway. This form of feedback inhibition prevents the excess of one or two of the amino acids from shutting down the entire pathway and thereby starving the cell for the third amino acid (Figure 7.34c).

Check Your Understanding

- What is feedback inhibition?
- What is the difference between an allosteric site and an active site?

7.16 Post-Translational Regulation

We have already discussed *phosphorylation* and *methylation*, two very common mechanisms for regulating a protein post-translationally, when we considered two-component regulatory systems and chemotaxis, respectively (Sections 7.5 and 7.6). Biosynthetic enzymes can also be regulated by the attachment of other small molecules, such as the nucleotides adenosine monophosphate (AMP), adenosine diphosphate (ADP), and uridine monophosphate (UMP). Throughout this chapter we have also encountered avenues in which the cell regulates the activity of proteins by protein–protein interactions. In contrast to these, some enzymes are regulated by *covalent modification*, typically the attachment or removal of a small molecule to or from the enzyme that subsequently affects its catalytic activity, and we consider this regulatory mechanism here.

Microbiology
Art Activity:
Figure 7.34a, b
Inhibition of
enzyme activity

Figure 7.34 Inhibition of enzyme activity. (a) In feedback inhibition, the activity of the first enzyme of the pathway is inhibited by the end product, thus shutting off the production of the three intermediates and the end product. (b) The mechanism of allosteric inhibition by the end product of a pathway. When the end

product binds at the allosteric site, the conformation of the enzyme is so altered that the substrate can no longer bind to the active site. However, inhibition is reversible, and end product limitation will once again activate the enzyme. (c) Inhibition by isoenzymes. In *Escherichia coli*, the pathway leading to the synthesis

of the aromatic amino acids contains three isoenzymes, each of which form a key intermediate, DAHP. Each isoenzyme is feedback-inhibited by a different aromatic amino acid. An excess of all three amino acids is required to completely shut off synthesis of DAHP and thus shut down the pathway.

Regulation of PII Signal Transduction Proteins

PII proteins are a widespread family of signal-transducing proteins (Section 7.5) found in *Bacteria*, *Archaea*, and the plastids of plants. PII proteins play an important role in nitrogen metabolism by regulating a diverse range of transcription factors, enzymes, and membrane transport proteins (we have already seen one instance of PII-based regulation with the Ntr system, Figure 7.14b). The activity of PII proteins on their regulatory cascade depends on whether they have been covalently modified or not. These modifications range from *uridylylation* (addition of a UMP group, Figure 7.14b), *adenylation* (addition of AMP), or even *phosphorylation* in some organisms. Because these covalent modifications affect protein activity and occur *after* the PII proteins have been fully synthesized, the regulation is *post-translational*. Here we consider PII and its uridylylation by GlnD, a bifunctional enzyme that possesses both uridylyltransferase activity and uridyl-removal activity in response to levels of the amino acid glutamine (Figure 7.35).

One of the main ways the cell determines if ammonia (NH_3) assimilation is necessary is through glutamine sensing by GlnD. If the cellular glutamine pool is low, it signals that NH_3 assimilation is necessary. GlnD transduces this signal through the binding of glutamine itself. When GlnD is not bound to glutamine, the enzyme possesses uridylyltransferase activity and adds a UMP group to PII, yielding PII-UMP by post-translational modification.

One protein target of PII-UMP within the nitrogen metabolism pathway is glutamine synthetase adenylyltransferase (Figure 7.35a). Once uridylylated, PII-UMP stimulates glutamine synthetase adenylyltransferase to remove adenylyl groups from glutamine synthetase (GS). GS is a key energy-requiring enzyme in ammonia (NH_3) assimilation (◀ Section 3.14) and must be tightly regulated to conserve energy if cellular levels of nitrogen are high, as sensed by the glutamine pool. As GS becomes less adenylylated, its activity *increases* and NH_3 assimilation increases (Figure 7.35c). Once glutamine levels are sufficient, the cell no longer needs to assimilate NH_3 . This results in GlnD binding to available glutamine, which stimulates the protein to remove uridyl groups from PII-UMP (Figure 7.35b). PII in its unmodified form stimulates glutamine synthetase adenylyltransferase to adenylylate GS, forming GS-AMP. Fully adenylylated GS is *less active* and thus NH_3 assimilation by way of GS diminishes.

Why does all this elaborate regulation surround the enzyme GS? It is basically a matter of conserving energy. Because it has such a high affinity for its substrate, GS can assimilate ammonia present at very low levels, but this capability comes at a cost—the expenditure of ATP. However, when NH_3 is present at high levels in the cell, it can be assimilated into amino acids by enzymes that do not consume ATP; under these conditions, GS in the cell remains inactive. Then, when NH_3 levels are low, GS activity increases. By having GS active only when NH_3 is limiting, the cell conserves ATP that could be used to drive other energy-consuming processes in the cell.

Inactivation of Sigma Factors

In Section 7.11 we described how the σ factor RpoH is inactivated by DnaK under normal temperature conditions in the heat shock response (Figure 7.27). Proteins known as *anti-sigma* factors can

Figure 7.35 Post-translational regulation of PII and glutamine synthetase. Glutamine synthetase is a key enzyme of ammonia incorporation, especially when ammonia is present at low concentrations, in all *Bacteria* and *Archaea* (◀ Section 3.14). (a) Uridylylation of PII and activation of glutamine synthetase (GS), a multi-subunit enzyme. In response to low cellular pools of glutamine, the uridylyltransferase activity of GlnD is stimulated. This converts PII to PII-UMP, which triggers glutamine synthetase adenylyltransferase to activate GS by removing AMP(s). (b) Removal of UMP from PII and inactivation of GS. In response to high cellular pools of glutamine, the UMP removal activity of GlnD is activated. This converts PII-UMP to PII, which triggers glutamine synthetase adenylyltransferase to inactivate GS through adenylylation. (c) Overall control of GS activity. Adenylylated GS subunits are catalytically inactive, so the overall GS activity increases progressively as glutamine levels decrease and more subunits are deadenylylated. Conversely, GS activity decreases progressively as glutamine levels increase and more subunits are adenylylated.

Figure 7.36 Anti-sigma-sigma factor interactions. (a) Sequestration of the RpoE sigma factor by the anti-sigma factor RseA. When the outer membrane is not stressed, cytoplasmic membrane-bound RseA binds to RpoE. This binding prevents the sigma factor from binding to promoters of genes for envelope repair and *dnaK*. (b) Inactivation of RseA and release of the RpoE sigma factor. When the outer membrane is exposed to stress, outer membrane proteins (OMPs) are denatured. These unfolded OMPs trigger proteolytic degradation of RseA. Without RseA, the RpoE sigma factor can bind to its promoter regions and transcribe genes for envelope stress and *dnaK* to help repair the membrane and refold proteins.

also bind to sigma factors, inactivating them in a form of post-translational regulation.

RpoE (σ^{24} or σ^E , ◀ Table 6.3) is a sigma factor widespread in *Bacteria* that responds to extracytoplasmic stress by recognizing promoters for genes that encode products necessary for proper folding, expression, and turnover of proteins that reside in the outer membrane (◀ Section 2.4). One of these promoters is for *dnaK*. Under nonstressful conditions, the membrane-bound anti-sigma factor RseA sequesters RpoE from binding to the promoters it targets (Figure 7.36a). However, if a cell encounters a condition stressful to the membrane such as heat or osmotic stress, outer membrane proteins are denatured, and this *activates* a protease specific for RseA (Figure 7.36b). Once RseA has been degraded, RpoE is free to activate transcription of genes necessary for cell envelope repair such as refolding outer membrane proteins and the synthesis of phospholipids and lipopolysaccharides. Release of RpoE also includes increasing the level of DnaK produced so that this chaperone (◀ Section 6.11) can assist with folding and turnover of outer membrane proteins as well.

Once the membrane has been repaired, RseA is no longer targeted for degradation and reassociates with the cytoplasmic membrane. In this form, RseA can resume its anti-sigma factor activity by binding and sequestering RpoE from promoter regions. This leads to a

decreased expression of both genes encoding products needed to respond to membrane stress and *dnaK*. Another well-studied example of regulation by anti-sigma-sigma interactions occurs during the formation of endospores in *Bacillus* when the anti-sigma factor SpoIIAB binds to σ^F , thereby preventing its association with RNA polymerase; we pick up on this control process in Section 8.6 and Figure 8.18.

Regardless of the mechanism, in the final analysis it should be clear that regulating the synthesis and activities of a cell's RNAs and proteins is (1) very important to its biology, (2) possible in many different ways, and (3) a major genetic investment. But the costs to the cell are worth it and are grounded in billions of years of evolutionary refinement. At every turn in a highly competitive world, a microbe's growth and very survival may well depend on its ability to conserve its resources and maximize its progeny.

Check Your Understanding

- What types of covalent modifications commonly alter the activity of proteins?
- How does GlnD signal to the cell that NH_3 assimilation is necessary?
- Explain the role of an anti-sigma factor.

CHAPTER REVIEW

Go to **Mastering Microbiology** for videos, animations, practice tests, and more.

I • DNA-Binding Proteins and Transcriptional Regulation

- 7.1** Proteins can bind to DNA when specific protein domains bind to specific regions of the DNA molecule. In most cases the interactions are sequence-specific.

Q Explain how a protein ensures that it binds specifically to only a certain region of DNA and not to another.

- 7.2** Transcription factors are DNA-binding proteins that control gene expression. Activator and repressor proteins are common transcription factors whose DNA binding is controlled by the presence or absence of effector molecules.

Q What is an allosteric protein?

- 7.3** The amount of a specific enzyme in the cell can be controlled by regulatory proteins that bind to DNA and increase (induce) or decrease (repress) the amount of mRNA that encodes the enzyme.

Q How is β -galactosidase induced in cells?

- 7.4** *Archaea* resemble *Bacteria* in using DNA-binding activator and repressor proteins to regulate gene expression at the level of transcription.

Q What are the two mechanisms used by archaeal repressor proteins to repress transcription?

II • Sensing and Signal Transduction

- 7.5** Signal transduction systems transmit environmental signals to the cell. In *Bacteria* and *Archaea*, signal transduction is typically carried out by a two-component regulatory system that includes a membrane-integrated sensor kinase and a cytoplasmic response regulator. The activity of the response regulator depends on its state of phosphorylation.

Q What are the two components that give their name to the signal transduction system in prokaryotic cells? What is the function of each of the components?

- 7.6** Chemotactic behavior allows cells to respond to attractants and repellents in their environment. The regulation of chemotaxis affects the activity of proteins rather than their synthesis. Adaptation by methylation allows the system to reset itself to the continued presence of a signal.

Q Adaptation allows the mechanism controlling flagellar rotation to be reset. How is this achieved?

- 7.7** Quorum sensing allows cells to monitor their environment for cells of their own kind. Quorum sensing depends on the sharing of specific small molecules known as autoinducers.

Once a sufficient concentration of the autoinducer is present, specific gene expression is triggered.

Q How can quorum sensing be considered a regulatory mechanism for conserving cell resources?

III • Global Control

- 7.8** Global control systems regulate the expression of many genes simultaneously. Catabolite repression is a global control system that helps cells make the most efficient use of available carbon sources. The *lac* operon is under the control of catabolite repression as well as its own specific negative regulatory system.

Q Describe the mechanism by which cAMP receptor protein (CRP), the regulatory protein for catabolite repression, functions. Use the lactose operon as an example.

- 7.9** The stringent and general stress responses are deployed to survive nutrient limitation and stresses by decreasing expression of genes for macromolecule biosynthesis and activating stress survival pathways.

Q Explain the sequence of molecular events that leads to the synthesis of (p)ppGpp in *Escherichia coli* during the stringent response.

- 7.10** The phosphate (Pho) regulon employs a two-component regulatory system to sense cellular levels of phosphate. The cytoplasmic transcriptional regulator of this regulon binds to promoter regions called Pho boxes and functions as either an activator or a repressor depending on phosphate levels in the cell.

Q Explain how the binding of Pho transcriptional regulator activates transcription of some genes within the Pho regulon, but not others.

- 7.11** Cells respond to excessive temperature and other stressors that lead to protein denaturation by employing the heat shock response. This response results in expressing sets of genes whose products help the cell overcome stress, including an alternative sigma factor.

Q Describe the proteins produced when cells of *Escherichia coli* experience a heat shock. Of what value are they to the cell?

IV • RNA-Based Regulation

- 7.12** Cells can control genes in several ways by employing regulatory RNA molecules. One way is to take advantage of base pairing and use small RNAs to promote or prevent translation of mRNAs.

Q What are the mechanisms by which regulation by sRNA occurs?

7.13 Riboswitches are sequences at the 5' ends of certain mRNAs that recognize small molecules and respond by changing their three-dimensional structure to affect translation or transcriptional termination of the mRNA. Riboswitches are mostly employed to control biosynthetic pathways for vitamins, amino acids, purines, and a few other metabolites.

Q What are the mechanisms by which riboswitches regulate translation and transcription?

7.14 Attenuation is a mechanism whereby transcription is controlled after initiation of mRNA synthesis. Attenuation mechanisms depend upon alternative stem-loop structures in the mRNA that result in either read-through or stalling of the ribosome.

Q Describe in detail how a tryptophan attenuator is controlled.

V • Regulation of Enzymes and Other Proteins

7.15 In feedback inhibition, an excess of the final product of a biosynthetic pathway inhibits an allosteric enzyme at the beginning of the pathway. Enzyme activity can also be modulated by isoenzymes.

Q Describe how feedback inhibition is reversible, and why are isoenzymes necessary for some forms of feedback inhibition?

7.16 Protein activity can be regulated after translation. Reversible covalent modification or interactions with other proteins can modulate protein activity.

Q How can post-translational modifications regulate the activity of an enzyme?

APPLICATION QUESTIONS

1. What would happen to regulation from a promoter under repression if the region where the regulatory protein binds was deleted? What if the promoter was under positive control? Promoters from *Escherichia coli* under positive control are not close matches to the promoter consensus sequence for *E. coli*. Why?
2. Most of the regulatory systems described in this chapter employ regulatory proteins. However, regulatory RNA is also important. Describe how one could achieve negative control of the *lac* operon using either of two different types of regulatory RNA.
3. Many amino acid biosynthetic operons under attenuation control are also under negative control. Considering that the environment of a bacterium can be highly dynamic, what advantage could be conferred by having attenuation as a second layer of control?
4. How would you design a regulatory system to make *Escherichia coli* use succinic acid in preference to glucose? How could you modify it so that *E. coli* prefers to use succinic acid in the light but glucose in the dark?

CHAPTER GLOSSARY

Activator protein a regulatory protein that binds to specific sites on DNA and stimulates transcription

Allosteric protein a protein containing an active site for binding substrate and an allosteric site for binding an effector molecule such as the end product of a biochemical pathway

Attenuation a mechanism for controlling gene expression that terminates transcription after initiation but before a full-length messenger RNA is produced

Autoinducer a small signal molecule that takes part in quorum sensing

Catabolite repression the suppression of alternative catabolic pathways by a preferred source of carbon and energy

Cyclic AMP a regulatory nucleotide that participates in catabolite repression

Domain region of a protein with specific structure and function

Enzyme induction production of an enzyme in response to a signal (often the presence of the substrate for the enzyme)

Enzyme repression prevention of the synthesis of an enzyme in response to a signal

Feedback inhibition a process in which an excess of the end product of a multistep pathway inhibits activity of the first enzyme in the pathway

Gene expression transcription of a gene followed by translation of the resulting mRNA into protein

Heat shock proteins proteins induced by high temperature (or certain other stresses) that protect against high temperature, especially by refolding partially denatured proteins or by degrading them

Heat shock response response to high temperature that includes the synthesis of heat shock proteins together with other changes in gene expression

Noncoding RNA (ncRNA) RNA that is not translated into protein; examples include ribosomal RNA, transfer RNA, and small regulatory RNAs

Operon two or more genes transcribed into a single RNA and under the control of a single regulatory site

Quorum sensing a regulatory system that monitors the population level and controls gene expression based on cell density

Regulatory nucleotide a nucleotide that functions as a signal rather than being incorporated into RNA or DNA

Regulon a series of operons controlled as a unit

Repressor protein a regulatory protein that binds to specific sites on DNA and blocks transcription

Response regulator protein one of the members of a two-component regulatory system; a protein that is phosphorylated by a sensor kinase and then acts as a regulator, often by binding to DNA

Riboswitch an RNA domain, usually in a messenger RNA molecule, that can bind a specific small molecule, altering its own secondary structure; this, in turn, controls translation of the mRNA

Sensor kinase protein one of the members of a two-component regulatory system; a protein that phosphorylates itself in response to an external signal and then transfers the phosphoryl group to a response regulator protein

Signal transduction see *two-component regulatory system*

Stringent response a regulatory mechanism that detects nutrient or environmental stresses and antibiotics

Transcription factor a regulatory protein that binds to specific sites on DNA and controls transcription; generally activator and repressor proteins

Two-component regulatory system a regulatory system consisting of two proteins: a sensor kinase and a response regulator

MICROBIOLOGYNOW

Membrane Vesicles: Nano Vehicles Transporting Important Cargo

Membrane vesicles are nano-sized structures (10–400 nm) released from cells of all three domains of life during membrane budding. These vesicles can contain a variety of biomolecules such as nucleic acids, carbohydrates, proteins, enzymes, toxins, and even viruses. Because of the lipid bilayer protecting the cargo, membrane vesicles are excellent vehicles for transferring substances between cells.

Remarkably, recent studies show that vesicle size and content are not random but are controlled by cellular signals. Thus, microbes are able to employ these tiny vehicles for an assortment of activities such as DNA exchange between cells, toxin delivery into host cells, reducing competition through antimicrobial release, and biofilm formation. The study here deals with the biofilm way of life.

Biofilms are slimy, three-dimensional microbial communities formed to withstand environmental challenges. One of the major requirements for biofilm formation is the release of sticky extracellular polymeric substances (EPS) to help hold the biofilm matrix together. The image on the left shows a scanning electron micrograph of the eukaryotic microbe *Candida albicans* (elongated cell) releasing membrane

vesicles (arrow) containing such polysaccharides for biofilm construction.

Pathogenic strains of *C. albicans* often form biofilms on indwelling medical devices, resulting in yeast infections that evade the immune system and are resistant to antifungal drugs. Microbiologists investigating methods to treat these impervious biofilms also discovered specific enzymes within the vesicles that modify the EPS in a manner that makes the biofilm resistant to antifungal agents (image to the right, arrow denotes EPS). By contrast, vesicles from free-living cells contain completely different cargo. Strains of *C. albicans* genetically modified to limit their vesicle production produced yeast biofilms sensitive to antifungal drugs.

Research on membrane vesicles highlights the importance of ongoing studies of microbial growth and how new targets for attack by therapeutic agents can be exposed by basic research to understand the molecular aspects of microbial growth.

In previous chapters we discussed the basic biology of microbes (Chapters 1–3 and Chapter 5) and how prokaryotic cells grow and divide (Chapter 4), replicate their chromosome(s) (Chapter 6), and regulate gene expression (Chapter 7). Here we follow up on the major concepts that unfolded in Chapter 4 with a focus on key molecular processes that occur in the microbial growth cycle. We also consider cellular differentiation in some model bacteria, revisit the process of biofilm growth, and close by exploring how some common antibiotics affect microbial growth and the weapons bacteria deploy to counter such attacks.

I • Bacterial Cell Division

Prokaryotic cell division is preceded by chromosome replication and the synthesis of new cell wall material in a way that defines cell shape. Cell division is orchestrated in a carefully controlled fashion by protein complexes whose activities can be visualized by powerful light microscopic techniques.

Most cells divide by binary fission (◀ Section 4.6 and Figure 4.8), and this process occurs in a defined series of steps such that each daughter cell obtains a copy of the genome. During the division cycle, the cell must also produce new peptidoglycan and cytoskeleton elements to prevent bursting from osmotic forces. This cytoskeleton gives the cell its distinct morphology (◀ Figure 1.8). To successfully orchestrate all of these events, various regulatory cascades are put into play. In this first part of the chapter we focus on the molecular mechanisms employed by two well-studied gram-negative bacteria, *Escherichia coli* and *Caulobacter crescentus*, and introduce advanced microscopic techniques that have revealed the major molecular events that underlie cell division and cell morphology.

8.1 Visualizing Molecular Growth

In Chapter 1 we discussed transmission electron microscopy and electron cryotomography as powerful techniques to visualize macromolecules such as chromosomes, proteins, and membranes. In addition to these, **super-resolution microscopy** is a powerful form of *light* microscopy that employs a suite of fluorescent molecules to reveal even the tiniest details within a cell. Super-resolution techniques can resolve structures as small as 5–50 nm in living cells, allowing for dynamic cellular behaviors to be observed in real time.

Fluorescent Tagging

To visualize the localization of specific proteins and to monitor gene expression in cells, **reporter genes** are valuable tools. Reporter genes encode proteins that are easy to detect or assay and are used by fusing them to genes of interest in such a way that both the reporter gene and the gene of interest are coexpressed. For visualizing molecular events, reporter genes that encode fluorescent products such as the **green fluorescent protein (GFP)** are routinely used (Figure 8.1). Through the use of fluorescence microscopy (◀ Section 1.8) and multiple fluorescent reporter proteins, the activity and localization of different macromolecules can be determined simultaneously.

Figure 8.1 Fluorescence micrographs illustrating molecular growth characteristics. (a) During endospore formation in *Bacillus*, alternative sigma factors are localized to specific regions of the cell (Section 8.6). σ^F linked to GFP indicates activity of the σ^F protein in the developing endospore (at one end of each cell). σ^E linked to a reporter protein that fluoresces red indicates expression and activity of the σ^E protein throughout the mother cell prior to endospore formation. Regions correspond to the model depicted in Figure 8.18b. (b) Location and orientation of the *Escherichia coli* chromosome during cell cycle progression (Section 8.2). Regions are visible due to tagged DNA-binding proteins targeting the *oriC* (green), left arm (red), and right arm (cyan). Modified from Woldringh, C.L., Hansen, F.G., Vischer, N.O.E., and Altung, T. 2015. *Front. Microbiol.* 6: 448. (c) Time-lapse series showing FtsZ (red) and MinD (green) in an elongated *E. coli* cell. Cell division was inhibited by antibiotic treatment and arrows indicate locations where unstable FtsZ proteins polymerize and depolymerize. Modified from Wu, F., Van Rijn, E., Van Schie, B.G.C., Keymer, J.E. and Dekker, C. 2015. *Front. Microbiol.* 6: 607. (d) Peptidoglycan synthesis in *Staphylococcus aureus*. The incorporation of amino acids is visible because a different fluorophore is linked to each D-amino acid present in peptidoglycan. The colors show that peptidoglycan synthesis begins at the septum region and continues in a concentric fashion around the growing cell. Modified from Pereira, A.R., et al., 2016. *MBio* 7(5): doi:10.1128/mBio.00908-16.

Figure 8.1a demonstrates use of GFP and another fluorescent protein to determine the cellular locations of σ^F and σ^E , two spore-specific sigma factors (◀ Section 6.5) that play key roles in endospore development in *Bacillus* (◀ Section 2.8 and Section 8.6).

Fluorescent tagging can also be used to resolve different genetic elements in a cell, such as a chromosome and a plasmid (see Figure 8.7). In fact, even different loci within an individual nucleic acid molecule can be observed in a living cell. While DNA or RNA loci are not linked directly to a reporter gene like GFP, genes encoding nucleic acid-binding proteins specific for target loci can be fused to a reporter gene. If necessary, the corresponding DNA or RNA binding sites can be introduced into the nucleic acid region of interest using recombinant techniques (Chapter 12). Figure 8.1b illustrates how separate “arms” of the *Escherichia coli* chromosome can be visualized in a living cell by engineering a strain to express different fluorescently tagged proteins that bind to different regions of the DNA.

Advances in protein labeling and microscopy techniques have yielded new fluorescent variant proteins that fold quickly and allow for visualization of both spatial and temporal protein dynamics in live cells. Figure 8.1c illustrates the spatiotemporal dynamics of MinD and FtsZ (proteins of the divisome, see Section 8.3) in a growing cell over a time-lapse series. Other cellular aspects can be visualized by linking individual fluorophores (small fluorescent chemical compounds) to specific molecules such as amino acids. For example, Figure 8.1d illustrates the dynamic synthesis of peptidoglycan in growing *Staphylococcus aureus* cells through the incorporation of three separately fluorophore-labeled amino acids present in the cell wall.

Super-Resolution Techniques

Although fluorescence microscopy enables observation of tagged internal cellular structures, resolution is insufficient to observe the molecular events occurring during the cell cycle. By contrast, super-resolution techniques can reveal and quantify elements as small as *single molecules* in living cells. Super-resolution techniques employ photoactivated probes that switch from bright to dark emission states depending on the wavelength of light that strikes them; this allows for only one fluorescent molecule (or target) to be excited at a time. By recording the position of individual molecules over time, a super-resolution image is generated (Figure 8.2a).

Super-resolution techniques can reveal the details of cellular superstructures, for example by precisely mapping the diffusion and movement of individual proteins. Figure 8.2a illustrates the use of *photoactivated localization microscopy*, a form of super-resolution microscopy, to map the movement of individual MukB molecules in a living *E. coli* cell. MukBEF is a protein complex that binds to the nucleoid and localizes to distinct regions in the cell to assist with unknotting daughter chromosomes after replication (Section 8.2). Not only can super-resolution microscopy be used to observe structural changes to cellular complexes over time, the micrographs can also be modified to construct three-dimensional (3D) images. Figure 8.2b illustrates the use of a super-resolution method called *3D subdiffraction* imaging to observe the arrangement of different protein complexes in the budding bacterium *Caulobacter crescentus*.

By providing spatiotemporal information about individual proteins, super-resolution techniques have been instrumental in proving that like their eukaryotic counterparts, prokaryotic cells contain a highly dynamic subcellular structural organization whose activities during the cellular growth process can be tracked at the molecular level. We now focus on some of these key molecular events as we revisit the growth cycle of prokaryotic cells in detail.

Check Your Understanding

- What is the utility of a reporter gene?
- What are the advantages of using super-resolution microscopy versus standard fluorescence microscopy?

8.2 Chromosome Replication and Segregation

A prerequisite for bacterial growth is replication of the genome. Chromosome replication must be tightly regulated to coincide with cell division. After genome replication and prior to cell division, molecular mechanisms must also ensure that the daughter

(a) Photoactivated localization microscopy (PALM) mapping the movement of the nucleoid-binding protein MukB in an individual *Escherichia coli* cell. The four different colors represent clusters of nucleoid-bound MukB molecules, while tracks corresponding to their movement are represented by black lines. Gray lines represent tracks of free MukB (Section 8.2). (b) Three-dimensional quantitative multicolor imaging of *Caulobacter* cellular structures. PopZ is tagged with a red fluorescent reporter, while crescentin (Section 8.4) is tagged with a green fluorescent reporter.

chromosomes are segregated (Figure 8.3). Because the process of cell division in bacterial and archaeal cells requires both temporal and spatial control elements, the process is controlled by a cell cycle (Figure 8.3). Temporally, two copies of the cell's genome must exist prior to cell division. Spatially, the two copies must be equally segregated and the septum must form at the correct location in the cell for a successful cell cycle to occur.

Regulation of Chromosome Replication Initiation

How does the cell ensure that the genome is completely replicated before cell division while also preventing multiple rounds of replication? Several different proteins play a role in initiating and

S. Uphoff and A. Badrinarayan

Alexander von Diezmann, Andreas Gahlmann, and W.E. Moerner, Stanford University

Figure 8.3 Overview of the bacterial cell cycle. Phases analogous to the growth 1 (G1), synthesis (S), and growth 2 (G2) phases of the eukaryotic cell cycle are represented.

inhibiting chromosome replication in *Escherichia coli*. Here we focus on a key protein in this regard, DnaA, along with a handful of accessory proteins necessary to complete replication initiation.

As we discussed in Section 6.3, binding of DnaA to specific DNA sequences within the *oriC* region of the chromosome leads to unwinding of the DNA and loading of the replisome for chromosome replication in *Escherichia coli* (Figure 8.3; to review DNA replication, see Figure 6.16). DnaA is most active when it is linked to a molecule of ATP, forming DnaA-ATP. To tightly control chromosome replication, multiple regulatory mechanisms come into play to inactivate DnaA-ATP once replication has initiated. These mechanisms include competition for *oriC* binding, repression of *dnaA* expression, titration of DnaA-ATP away from *oriC*, and inactivation of DnaA-ATP.

Before DNA replication initiates, both strands of the chromosome contain methyl groups on the adenine residue of –GATC– sequences within the chromosome. However, immediately after replication has initiated, only the parental strand remains methylated. This results in *hemimethylated DNA* and facilitates a competition for origin binding between DnaA-ATP and a DNA-binding protein called SeqA (Figure 8.4). Because hemimethylated *oriC* sequences are strongly bound by SeqA, DnaA-ATP is blocked from binding and reinitiating chromosome replication (Figures 8.3 and 8.4). Approximately 10 min after replication has initiated, GATC sequences within the newly synthesized daughter strand are methylated by a DNA adenine methylase.

As a result of the chromosomal proximity of the *dnaA* gene to *oriC* and of the promoter region (◀ Section 6.5) of *dnaA* possessing a GATC sequence, binding of SeqA also plays a role in repressing the expression of *dnaA*. Once replication has initiated, the promoter region for *dnaA* is quickly hemimethylated, and the binding of SeqA prevents RNA polymerase from binding and transcribing *dnaA* (Figure 8.4). Subsequently, expression of *dnaA* is also *autoregulated* by its corresponding protein binding to DnaA boxes within its promoter region.

The final mechanism of preventing DnaA-ATP from binding *oriC* is to decrease the ratio of DnaA-ATP to DnaA-ADP. How does the cell increase the level of DnaA-ADP when ATP dominates over ADP in a growing cell? This is controlled by the ATPase HdaA, which associates with DNA in the proximity of the replisome and specifically targets DnaA-ATP. This enzyme promotes the hydrolysis of ATP associated with DnaA in a replication-dependent manner and thus

Figure 8.4 Binding of the *Escherichia coli* *oriC* by DnaA and SeqA proteins. DnaA-ATP only binds to fully methylated DnaA boxes, while SeqA binds to hemimethylated DNA. The binding of SeqA upstream of the *dnaA* gene leads to repression of transcription.

functions as a final method of regulating the initiation of chromosome replication. As a result of these combined mechanisms, the cellular level of DnaA–ATP oscillates during the cell cycle, reaching the maximum active amount when initiation of chromosome replication is needed and waning thereafter.

Genome Replication in Fast-Growing Cells

As we learned in Chapter 6, the circular nature of the chromosome of *E. coli* (and that of most other *Bacteria* and *Archaea*) creates an opportunity for speeding up DNA replication. This is because replication of circular genomes is *bidirectional* from the origin of replication. During bidirectional replication, synthesis occurs in both leading and lagging directions on each template strand, and this allows DNA to replicate as rapidly as possible (◀ Figure 6.15). Studies of chromosome replication in *E. coli* have shown that about 40 min is required for genome replication and that this value is independent of the generation time, which in *E. coli* can be as little as 20 min. If an *E. coli* cell is growing at twice the rate that its chromosome is replicating, how does the cell resolve this conundrum?

In cells growing at doubling times shorter than 40 min, *multiple DNA replication forks* are present in each cell. That is, a new round of DNA replication begins before the last round has been completed (Figure 8.5); as a result, some genes are present in more than one copy. This can occur after the DNA in the *oriC* region of the newly synthesized DNA has been methylated, which releases SeqA from the DNA and allows DnaA–ATP to be recruited to reinitiate another round of replication (Figure 8.4). This ensures that at generation times shorter than the time required for replication (a process that occurs at a constant and maximal speed), each daughter cell receives a complete genome at the time of septum formation.

Chromosome Segregation

During cell division, segregation of the chromosomes to the cell poles is needed not only to ensure that each daughter cell gets a copy of the genome, but also to allow for septum formation (Figure 8.3). If the two copies of the nucleoid remained in the center of the cell, nucleoid occlusion (a process that prevents the cell from dividing across the nucleoids) would impede proper cell division. In eukaryotes, mitotic spindles separate replicated chromosomes in mitosis (◀ Section 2.13). In many bacteria including the budding bacterium

(a) Generation time, 1 h; replication time, 40 min.

(b) Generation time, 20 min; replication time, 40 min.

Figure 8.5 Genome replication in cells of *Escherichia coli* growing at 60-min or 20-min generation times. In cells doubling every 20 min, multiple replication forks ensure that each daughter cell gets a complete copy of the genome, which takes 40 min to replicate. In cells doubling every 60 min, multiple replication forks are unnecessary.

Caulobacter, a similar mechanism called the *Par* (partitioning) system is used to distribute chromosomes and plasmids equally to progeny cells during growth (Figure 8.6). This system is composed of the ParA ATPase, the ParB chromosome-binding protein, and the PopZ complex, as well as a centromere-like *parS* sequence located near *oriC*.

Unlike eukaryotic mitotic spindles, the *Par* system does not segregate fully replicated chromosomes. Instead, PopZ proteins localize to the stalked pole of the cell and facilitate anchoring of the chromosome to this location by interacting with ParB bound to the *parS* sequence (Figure 8.6). Once chromosome replication initiates, the newly synthesized *parS* sequence binds to another molecule of ParB, which is then pulled to the stalked pole by the ATPase activity of ParA. Not only does PopZ help anchor *parS* of the parent chromosome to the stalked pole of the cell, it also helps recruit ParA to transfer the newly synthesized *parS* sequence bound to ParB to the nonstalked cell pole (Figure 8.6).

While *E. coli* lacks the *Par* system, the daughter chromosomes must still be segregated prior to cell division. After replication the resulting circular chromosomes remain interlinked or tangled, much like the links in a chain. This linkage is broken by the *structural maintenance of chromosome* complex, which is composed of a topoisomerase (IV) (◀ Section 6.1) and MukBEF proteins. Super-resolution images show that the MukBEF proteins move to discrete locations within the nucleoid (Figure 8.2a) and recruit a topoisomerase to separate replicated

Figure 8.6 Chromosome partitioning in *Caulobacter*. After replication initiates, PopZ localizes to the stalked pole of the cell. Next, ParB binds to the *parS* sequence on the parental chromosome and the complex associates with PopZ at the pole. As replication continues, the *parS* sequence on the daughter chromosome is bound by ParB and moved to the nonstalked cell pole by the activity of diffuse ParA molecules. The location of FtsZ during partitioning is indicated.

Figure 8.7 Cellular location of ColE1 plasmid in *Escherichia coli* during replication. The plasmid (yellow) localizes to the cell poles, while the nucleoid remains in the center of the cell during DNA replication. The separate DNA molecules are visible due to fluorescently labeled DNA-binding proteins.

sister chromosomes (a process called *decatenation*) prior to segregation. While the actual segregation process is still not completely understood, the chromosome “arms” appear to remain distinctly separated from one another during replication and the chromosomal loci are pushed to the cell poles in their order of replication (Figure 8.1b). This separation of daughter chromosomes in *E. coli* thus appears to be independent of specific proteins and proceeds instead by the physical action of replication and DNA accumulation.

How are extrachromosomal genetic elements segregated between daughter cells? Although plasmids are not considered essential for cell survival under all conditions, they are replicated using the same cellular machinery as the chromosome (Figure 8.7). Various control mechanisms exist to ensure that a relatively constant copy number of a given plasmid is disseminated to progeny cells. Replication of large ColE1-type plasmids occurs at the poles instead of in the center of the cell where the nucleoid exists (Figure 8.7). This location helps ensure that efficient transfer to daughter cells occurs during cell division and that stable inheritance is achieved over generations. Other mechanisms for segregating plasmids include partitioning systems similar to the *Par* system in *Caulobacter* (Figure 8.6).

- How does SeqA prevent DnaA-ATP from binding to the *oriC* regions immediately after chromosome replication initiates?
- Explain how the minimum generation time for the bacterium *Escherichia coli* can be less than the time needed to replicate its chromosome.

8.3 Cell Division and Fts Proteins

Cell division is both spatially and temporally controlled to ensure that each daughter cell has a copy of the genome before the septum seals off the two cells (Figure 8.3). Here we consider regulation of septum formation and a series of key proteins that identify the site of cell division and control the overall process.

The Divisome

Several essential proteins play roles in cell division in *Bacteria*. Collectively, these proteins are called *Fts proteins* and a key one, **FtsZ**, plays a crucial role in binary fission. FtsZ is related to tubulin, the

important cell-division protein in eukaryotes (◀ Section 2.15) and is also found in virtually all *Archaea*. Other Fts proteins are found only in *Bacteria* and not in *Archaea*, so our discussion here will be restricted to the *Bacteria*. The gram-negative *Escherichia coli* and the gram-positive *Bacillus subtilis* have been the model bacterial species for the study of cell-division events.

Fts proteins interact in the cell to form a division apparatus called the *divisome*. In rod-shaped cells, formation of the divisome begins with the attachment of molecules of FtsZ in a ring precisely around the center of the cell; this ring becomes the cell-division plane. In a cell of *E. coli*, about 10,000 FtsZ molecules polymerize to form the ring; once formed, the FtsZ ring attracts other divisome proteins, including FtsA and ZipA (Figure 8.8). ZipA is an anchor that connects the FtsZ ring to the cytoplasmic membrane and stabilizes it. FtsA, a protein related to actin, an important cytoskeletal protein in eukaryotes (◀ Section 2.15), both recruits FtsZ and other divisome proteins and helps connect the ring to the cytoplasmic

Blowup shows the arrangement of individual divisome proteins. ZipA is an FtsZ anchor, FtsI is a peptidoglycan biosynthesis protein, FtsK assists in chromosome separation, and FtsA is an ATPase. (b) Appearance and breakdown of the FtsZ ring during the cell cycle of *Escherichia coli*. Microscopy: upper row, phase-contrast; bottom row, cells stained with a specific reagent that binds to FtsZ. Cell division events: first column, FtsZ ring not yet formed; second column, FtsZ ring appears as nucleoids start to segregate; third column, full FtsZ ring forms as cell elongates; fourth column, breakdown of the FtsZ ring and cell division. Marker bar in upper left photo, 1 μm .

membrane. The divisome forms about three-quarters of the way into the cell-division cycle. However, long before the divisome forms, the cell has already begun to elongate and DNA replication has begun (see Figure 8.9).

The divisome also contains Fts proteins needed for peptidoglycan synthesis, such as FtsI (Figure 8.8). FtsI is one of several *penicillin-binding proteins* present in the cell. Penicillin-binding proteins are so named because their activities are inhibited by the antibiotic penicillin (Section 8.5). The divisome orchestrates synthesis of new cytoplasmic membrane and cell wall material, called the *division septum*, at the center of a rod-shaped cell until the cell reaches twice its original length. Following elongation, the septum forms and the cell divides, yielding two daughter cells (Figure 8.3).

Min Proteins and Cell Division

DNA replicates before the FtsZ ring forms (Figure 8.9) because the ring forms in the space *between* the duplicated nucleoids; before the nucleoids segregate, they effectively block formation of the FtsZ ring in a process known as nucleoid occlusion (Section 8.2). The proteins MinC, MinD, and MinE interact to help guide FtsZ to the cell midpoint. MinD forms a spiral structure on the inner surface of the cytoplasmic membrane and helps to localize MinC to the cytoplasmic membrane. The MinD spiral oscillates back and forth along the

Figure 8.9 DNA replication and cell-division events. The protein MinE directs formation of the FtsZ ring and divisome complex at the cell-division plane. Shown is a schematic for cells of *Escherichia coli* growing with a doubling time of 80 min. MinC and MinD are most abundant at the cell poles during FtsZ ring formation.

long axis of the growing cell and functions to *inhibit* cell division by preventing the FtsZ ring from forming (Figure 8.9). Simultaneously, however, MinE also oscillates from pole to pole, and as it does, it functions to sweep MinC and MinD aside. Hence, because MinC and MinD dwell longer at the poles than anywhere else during their oscillation cycle, the center of the cell will have, on average, the lowest concentration of these proteins. As a result, the cell center becomes the most permissive site for FtsZ binding and so the FtsZ ring forms there. In this unusual series of events, the Min proteins ensure that the divisome forms only at the *cell center* and not at the cell poles (Figure 8.9).

As cell elongation continues and septum formation begins, the two copies of the chromosome are pulled apart, each to its own daughter cell (Figure 8.9). The Fts protein *FtsK* and several other proteins assist in this process. As the cell constricts, the FtsZ ring begins to depolymerize, triggering the inward growth of wall materials to form the septum and seal off one daughter cell from the other. The enzymatic activity of FtsZ also hydrolyzes guanosine triphosphate (GTP, an energy-rich compound) to yield the energy necessary to fuel the polymerization and depolymerization of the FtsZ ring (Figures 8.8 and 8.9).

In the budding bacterium *Caulobacter*, MinC and MinD are absent. Instead, a protein called MipZ (*midcell positioning of FtsZ*) controls the assembly site of FtsZ. During chromosome segregation, FtsZ localizes to the nonstalked pole of the cell with the chromosome terminus (Figure 8.6). MipZ forms a gradient throughout the cell by directly binding to the ParB–*parS* complex that facilitates chromosome segregation to the nonstalked cell pole as indicated in Figure 8.6. Once MipZ reaches the nonstalked pole, it displaces polar-localized FtsZ to the center of the cell for septum formation. The timeline for this process in *Caulobacter* is the same as for the Min system of *E. coli* (Figure 8.9).

Why do we need to know such intricate details of the cell division process? Besides understanding the molecular biology of microbial growth for purely scientific reasons, there are significant practical reasons for understanding the details of bacterial cell division. Such knowledge could lead to the development of new drugs that target specific steps in the growth cycle of pathogenic bacteria. As with penicillin (a drug that targets bacterial cell wall synthesis), the discovery of drugs that interfere with the function of specific Fts or other cell-division proteins could have broad applications in clinical medicine. In a world where the efficacy of many widely used antibiotics is rapidly fading because of exploding pathogen resistance, the need for new antibacterial antibiotics becomes ever more critical.

- How does FtsZ find the cell midpoint of a rod-shaped cell?

8.4 Determinants of Cell Morphology

Just as specific proteins direct cell *division* in bacteria, other specific proteins form the cell *cytoskeleton*. The cytoskeleton is the scaffolding that directs cell *shape*, yielding the spheres, spirals, crescents, and other morphologies typical of bacterial cells (◀ Figure 1.8). Interestingly, these shape-determining proteins, known as *SEDS* (shape, elongation, division, and sporulation) *proteins*, show

Figure 8.10 MreB and crescentin as determinants of cell morphology. (a) The cytoskeletal protein MreB is an actin analog that moves in tracks perpendicular to the long axis of a rod-shaped cell, making contact with the cytoplasmic membrane in several locations (indicated by arrows). The blowup shows the arrangement of individual elongasome proteins with MreB. RodZ anchors the complex, while MreA and MreC are structural proteins. RodA and class A and B penicillin-binding proteins (aPBP and bPBP) coordinate to synthesize new peptidoglycan. (b) Photomicrographs of the same cells of *Bacillus subtilis*. Left, phase-contrast; right, fluorescence. The cells contain a substance that makes the MreB protein fluoresce, shown here as bright white. (c) Cells of *Caulobacter crescentus*, a naturally curved (vibrio-shaped) cell. Cells are stained to show the shape-determining protein crescentin (red), which lies along the concave surface of the cell, and with DAPI, which stains DNA and thus the entire cell (blue).

significant homology to key cytoskeletal proteins in eukaryotic cells (◀ Section 2.15). Thus, like eukaryotes, bacteria possess a dynamic and multifaceted cell cytoskeleton.

Cell Shape and MreB

The major shape-determining factor in *Bacteria* is the protein MreB that forms a simple cytoskeleton in *Bacteria* and in a few species of *Archaea*. MreB forms patchlike filaments just below the cytoplasmic membrane that follow the natural curves of the cell (Figure 8.10). The MreB cytoskeleton defines cell shape by recruiting other proteins that function in cell wall growth, such as RodA (peptidoglycan synthesis; Figure 8.10a and Section 8.5), to form the *elongasome*. Inactivation of the gene encoding MreB or other proteins in the elongasome causes rod-shaped bacteria to become coccus-shaped. Moreover, most naturally occurring coccoid bacteria lack the *mreB* and *rodZ* genes and thus do not make MreB or RodZ. This implies that the “default” morphology for a bacterium is a sphere. Variations in the arrangement of MreB filaments in cells of nonspherical bacteria are likely responsible for the different common morphologies of prokaryotic cells.

How does MreB define a cell’s shape? The filament structures formed by MreB (Figure 8.10a) are not static, but instead passively move from one side to the other within the cytoplasm of a growing cell. MreB filaments and other associated proteins localize the synthesis of peptidoglycan (Section 8.5) at points where the rod-shaped filaments contact the cytoplasmic membrane (Figure 8.10a). This allows new cell wall to form at several points along the cell rather than from a single location at the FtsZ site outward, as in spherical bacteria (see Figure 8.13). By moving progressively in tracks perpendicular to the cell cylinder and initiating cell wall synthesis at multiple sites along the cell wall, MreB helps direct new wall synthesis in such a way that a rod-shaped cell elongates only along its long axis with cell wall synthesis dispersed at intervals (Figure 8.10b).

Crescentin

In the vibrio-shaped bacterium *Caulobacter*, a shape-determining protein called *crescentin* is present in addition to MreB. Copies of crescentin organize into filaments about 10 nm wide that localize onto the concave face of the curved cell (Figure 8.2b). The arrangement and localization of crescentin filaments impart the characteristic curved morphology to the *Caulobacter* cell (Figure 8.10c). *Caulobacter* is an aquatic bacterium that undergoes a life cycle in which swimming cells, called *swimmers*, eventually form a stalk and attach to surfaces. Attached cells then undergo cell division to form new swimmer cells that are released to colonize new habitats (see Section 8.8 and Figure 8.20). The steps in this life cycle are highly orchestrated at the genetic level, and because of this, *Caulobacter* has been used as a model system for the study of gene expression in cellular differentiation. Although crescentin seems to be unique to *Caulobacter*, proteins similar to crescentin have been found in other curved cells, such as the bacterium that causes peptic ulcers, *Helicobacter pylori*. This suggests that these proteins may be necessary for the formation of curved cells.

Evolution of Cell Division and Cell Shape

How do the determinants of cell shape and cell division in *Bacteria* compare with those in eukaryotes? While MreB functions similarly to the eukaryotic protein actin, FtsZ is both structurally and

functionally related to the eukaryotic protein tubulin. Actin forms structures called *microfilaments* that function as scaffolding in the eukaryotic cell cytoskeleton and in cell division, whereas tubulin forms *microtubules* that are important in mitosis and other processes. In addition, the shape-determining protein crescentin in *Caulobacter* is related to the keratin proteins that make up *intermediate filaments* in eukaryotic cells. Intermediate filaments form part of the eukaryotic cytoskeleton, and genes encoding similar proteins have been found in some other *Bacteria*. It thus appears that several proteins that control cell division and the cell cytoskeleton in eukaryotic cells (◀ Section 2.15) have evolutionary roots in the *Bacteria*. However, with the exception of FtsZ, genes encoding homologs of these proteins appear to be absent from most *Archaea*.

While our focus has been on the filament proteins MreB and crescentin in bacteria that grow by synthesizing new peptidoglycan at the center of the cell (or dispersively), a diversity of morphologies exists in the bacterial world. This is especially evident in species of *Alphaproteobacteria* (Figure 8.11), gram-negative bacteria that show not only significant morphological diversity but also significant metabolic diversity (Chapters 14 and 16). Hence, *Alphaproteobacteria* fill a host of diverse ecological niches in nature, from soil and water to symbiotic plant and animal associations.

Figure 8.11 Phylogeny and morphology of select diverse *Alphaproteobacteria*.

The tree was constructed from comparative sequences of *rpoC*, a gene encoding one of the subunits of RNA polymerase. *Escherichia coli*, a member of the *Gamma-proteobacteria*, is included for comparison. Colored shading represents areas of new peptidoglycan synthesis as indicated. Note the extensive morphological diversity within the *Alphaproteobacteria*. UNIT 2

Figure 8.12 Polar growth of *Agrobacterium tumefaciens*. A time series of fluorescent micrographs showing an *A. tumefaciens* cell following addition of a fluorescently labeled D-amino acid. The cell cycle progression shows addition of new peptidoglycan to one cell pole prior to septum formation and cell division.

Besides growing as rod-shaped cells and producing new cell material as we have seen in Figures 8.8–8.10, the *Alphaproteobacteria* contain species that can grow by synthesizing peptidoglycan at the poles (polar elongation). *Agrobacterium tumefaciens*, a plant pathogen, elongates at one pole in a process called unipolar elongation (Figure 8.12). Although rod-shaped, *Agrobacterium* lacks MreB. Instead peptidoglycan synthesis occurs at one pole before initiating at the midcell for cell division. For cell division to occur at the midcell, *Agrobacterium* does possess FtsZ. However, FtsZ resides in the growing pole during unipolar growth and then moves to midcell to recruit the peptidoglycan synthesis machinery and form the ring where the septum forms. It is thought that proteins within the divisome (Section 8.3) help sequester FtsZ in the growing pole during unipolar growth.

Other genera of *Alphaproteobacteria* grow in a process known as budding. Budding results in diverse cell morphologies (Figure 8.11; ◀ Section 4.10) and is a consequence of synthesizing peptidoglycan at various regions within the cell. However, the precise positioning of the peptidoglycan-synthesizing machinery in budding cells has yet to be discovered. Figure 8.11 also illustrates a principle we will see repeated many times in this book: The phylogenetic position of a bacterium cannot be predicted from its morphology and vice versa. With only rare exception (for example, the spirochetes, ▶ Section 15.17), morphology and phylogeny are unrelated characteristics.

Check Your Understanding

- How does MreB control the shape of a rod-shaped bacterium?
- What protein is thought to control the shape of cells of *Caulobacter*?
- What relationships exist between cytoskeletal proteins in *Bacteria* and those in eukaryotes?

8.5 Peptidoglycan Biosynthesis

In cells of *Bacteria* that contain peptidoglycan—and virtually all species do—preexisting peptidoglycan has to be temporarily severed to allow newly synthesized peptidoglycan to be inserted during the growth process. As we have just seen in rod-shaped cells, new cell wall grows at several locations along the length of the cell (Figure 8.10a, b), and it is localized in those cells that divide by polar elongation or

budding. By contrast, new cell wall material in cocci grows out in opposite directions from the FtsZ ring (Figure 8.13). Because cocci do not possess the SEDS proteins MreB and RodZ (Section 8.4), FtsZ plays a critical role in maintaining cell shape in cocci. Figure 8.14 illustrates cell division and peptidoglycan synthesis in the gram-positive coccus *Staphylococcus aureus*, as well as the irregular elongation that occurs in an *S. aureus* FtsZ mutant. Without a fully functional FtsZ, *S. aureus* cells begin to elongate and form curved cytoskeletons that illustrate the importance of SEDS proteins in maintaining cellular morphology.

Regardless of the mechanism a bacterium uses to maintain its cytoskeleton, a growing bacterial cell must both synthesize new peptidoglycan and export it outside the cytoplasmic membrane to link up with existing cell wall material, and we consider this problem here.

A. Umeda and K. Amako

Figure 8.13 Cell wall synthesis in gram-positive *Bacteria*. (a) Localization of cell wall synthesis during cell division. In cocci, cell wall synthesis (shown in green) is localized at only one point (compare with Figure 8.10a). (b) Scanning electron micrograph of cells of *Streptococcus pyogenes* showing wall bands (arrows). A single cell is about 1 μm in diameter.

Figure 8.14 *Staphylococcus aureus* cell division and FtsZ. Time-lapse series of fluorescence micrographs illustrating cell division in the wild type and an FtsZ mutant strain. Cell wall material is stained green, while membrane material is stained red. Wild-type cells form a septum for cell division at midcell and retain a coccus shape, while the mutant cells form an irregular elongated morphology. Modified from Pereira, A.R., et al. 2016. *MBio* 7(5); doi:10.1128/mBio.00908-16.

Insertion of New Peptidoglycan

Peptidoglycan can be thought of as a stress-bearing fabric, much like a thin sheet of rubber. Synthesis of new peptidoglycan during growth requires the controlled cutting of preexisting peptidoglycan along with the simultaneous insertion of peptidoglycan precursors. A lipid carrier molecule called *bactoprenol* plays a major role in the latter process. Bactoprenol is a hydrophobic C₅₅ alcohol that is bonded to an *N*-acetylglucosamine/*N*-acetylmuramic acid/pentapeptide peptidoglycan precursor to form *lipid II* (Figure 8.15). Bactoprenol transports peptidoglycan precursors across the cytoplasmic membrane by rendering lipid II sufficiently hydrophobic to pass through a transmembrane ABC transporter (◀ Figure 2.6) known as *flippase* (Figure 8.16a).

Figure 8.15 Bactoprenol (undecaprenol diphosphate). This highly hydrophobic molecule carries cell wall peptidoglycan precursors through the cytoplasmic membrane. The entire molecule is called lipid II.

Once outside the cell, lipid II interacts with peptidoglycan polymerases called *transglycosylases* that insert peptidoglycan precursors into a growing point in the cell wall and catalyze glycosidic bond formation (the remaining bactoprenol is then recycled to the cytoplasm to begin a new round of precursor transport). However, prior to insertion of the peptidoglycan precursor, small gaps in the existing peptidoglycan are made by enzymes called *autolysins*, enzymes that function to hydrolyze the bond that connects *N*-acetylglucosamine with *N*-acetylmuramic acid in the peptidoglycan backbone. The peptidoglycan precursor is then added across the gaps (Figure 8.16a). The junction between new and old peptidoglycan forms a ridge on the cell surface of gram-positive bacteria that can be observed by electron microscopy as a *wall band* (Figure 8.13b).

Peptidoglycan synthesis must be a highly coordinated process, and peptidoglycan precursors must be readily available during autolysin activity. This is because tetrapeptide units must be spliced into existing peptidoglycan immediately after autolysin activity in order to prevent a breach in the peptidoglycan fabric at the splice point; a breach could cause osmotic issues for the cell and lead to spontaneous cell lysis, called *autolysis*.

Transpeptidation

The final step in peptidoglycan synthesis is transpeptidation. Transpeptidation forms the peptide cross-links between muramic acid residues in adjacent glycan chains (◀ Section 2.3 and Figures 2.8 and 2.9). In gram-negative bacteria such as *Escherichia coli*, cross-links form between diaminopimelic acid (DAP) on one peptide and

Figure 8.16 Peptidoglycan synthesis. (a) Flippase transports lipid II across the cytoplasmic membrane to the growing point of the cell wall. Autolysin breaks glycolytic bonds in preexisting peptidoglycan, while transglycosylase synthesizes them, linking old peptidoglycan with new. (b) The transpeptidation reaction that leads to the final cross-linking of two peptidoglycan chains. Penicillin inhibits this reaction. G, *N*-acetylglucosamine; M, *N*-acetylmuramic acid.

D-alanine on the adjacent peptide. Although there are two D-alanine residues at the end of the peptidoglycan precursor, only one remains in the final molecule, as the other is removed during transpeptidation (Figure 8.16b). This reaction is exergonic (energy-releasing, Section 3.1) and supplies the energy necessary to drive transpeptidation forward. In *E. coli*, the protein FtsI (Figure 8.8a) functions as the transpeptidase.

Transpeptidation is medically noteworthy because it is the reaction inhibited by the antibiotic penicillin. Several penicillin-binding proteins have been identified in bacteria, including FtsI (Figure 8.8a). When penicillin is bound to penicillin-binding proteins, the proteins are inactivated. If transpeptidation is blocked in an otherwise growing cell, the continued activity of autolysins (Figure 8.16a) so weakens the peptidoglycan that the cell eventually bursts. The absence of peptidoglycan in eukaryotes (such as humans) is the basis of the clinical efficacy of penicillin—the antibiotic destroys only growing bacteria and thus targets pathogenic bacteria that often grow rapidly in an active infection.

Morphology-Related Proteins and Peptidoglycan Synthesis

Many penicillin-binding proteins are bifunctional and possess not only transpeptidase activity but also transglycosylase activity (Figure 8.16). Unlike the protein domains in the transpeptidase, the transglycosylase domains are not inhibited by β -lactam antibiotics such as penicillin (Section 8.11). These proteins, known as class A penicillin-binding proteins (aPBPs), were previously considered the only proteins to perform peptidoglycan polymerization. However, studies of cell wall biosynthesis in both *Bacillus subtilis* and *Escherichia coli* have identified alternative SEDS proteins (Section 8.4) that help form new cell wall material through transglycosylase activity.

By genetically deleting all aPBP proteins in *B. subtilis* and *E. coli*, microbiologists have discovered that the elongasome proteins RodA and MreB, which were thought to only play roles in defining cell shape by localizing aPBPs to specific locations within growing cells for peptidoglycan synthesis (Figure 8.10a), can themselves add disaccharide precursors to the growing polypeptide chain. However, the SEDS family of proteins do not appear to have transpeptidase activity. Instead, class B penicillin-binding proteins (bPBPs), which lack transglycosylase activity, form the cross-links in peptidoglycan in the absence of aPBPs (Figures 8.10a and 8.16b).

Thus, and perhaps not surprisingly, bacteria have more than one distinct enzyme system available for synthesizing such a critical cellular component as the cell wall. Moreover, because SEDS are more widely distributed among *Bacteria* than are aPBPs, this explains how microorganisms lacking aPBPs can still synthesize peptidoglycan. It also highlights the possibility that SEDS proteins could be targets for new antibiotic development, as this family of proteins is not inhibited by β -lactams that bind and inactivate classical penicillin-binding proteins.

We move on now to Part II where we will explore developmental processes in bacteria. As in higher organisms where coordinated developmental changes result in new structures, some bacteria undergo transformations from one type of cell to another to either improve their chances of survival or allow them to be more successful in their habitat.

- What is the function of bactoprenol?
- What is transpeptidation, and why is it important both to the cell and to clinical medicine?

II • Regulation of Development in Model *Bacteria*

The formation of endospores in *Bacillus* and cell differentiation in *Caulobacter* are excellent models of developmental events in individual cells. The transitions between swimming and biofilms in *Pseudomonas* and *Vibrio* are valuable models of developmental events in cell populations.

Now that we have an understanding of the basic molecular processes that occur during bacterial growth, we move on to explore how certain bacteria differentiate to form specialized cells and how bacteria can transition from growing in suspensions (planktonic growth) to form multicellular biofilms.

Development and differentiation are largely characteristics one associates with multicellular organisms. Because most *Bacteria* and *Archaea* grow as single cells, few species show differentiation. But a few important examples are known and are classical cases of differential gene expression yielding two genetically identical descendants whose functions differ. Here we discuss three well-studied examples of development and differentiation: the formation of endospores in the gram-positive soil bacterium *Bacillus*; the formation of two cell types—motile and stationary—in the gram-negative aquatic bacterium *Caulobacter*; and the formation of heterocysts in the nitrogen-fixing cyanobacterium *Anabaena*. We conclude by considering the formation of biofilms in the gram-negative and pathogenic bacteria *Pseudomonas aeruginosa* and *Vibrio cholerae*.

8.6 Regulation of Endospore Formation

Many microorganisms respond to adverse conditions by converting growing (vegetative) cells into rigid and resistant spores (◀ Section 2.8 and Figure 2.29). Once favorable conditions return, the spore germinates, and the organism returns to the vegetative state (see Figure 8.19 and Section 8.7). Among *Bacteria*, the genus *Bacillus* is well known for the formation of *endospores*, that is, spores formed inside a mother cell (Figure 8.17). Prior to endospore formation, the cell divides asymmetrically. The smaller cell develops into the endospore, which is surrounded by the larger mother cell (Figure 8.17). Once development is complete, the mother cell bursts, releasing the endospore.

Endospore Formation: Sporulation Factors

Endospore formation in *Bacillus subtilis*, a model species for endospore studies, is triggered by unfavorable conditions, such as starvation, desiccation, or growth-inhibitory temperatures. A cell of *B. subtilis* monitors its environment through a group of five sensor kinases. These enzymes function via a phosphotransfer relay system whose mechanism resembles that of a two-component regulatory system (◀ Section 7.5) but is considerably more complex (Figure 8.18). The net result of multiple adverse conditions is the successive phosphorylation of several proteins called *sporulation factors*, culminating with sporulation factor Spo0A. When Spo0A is highly phosphorylated, sporulation proceeds. Spo0A controls the expression of several sporulation-specific genes. The product of one of these, SpoIIE, removes the phosphate from SpoIIAA, and this

Figure 8.17 *Bacillus* endospore elasticity map. Atomic force microscopy combined with a nanochemical surface map illustrating rigidity and release of endospore from mother cell. Flat white regions are indicative of rigidity, while dark regions illustrate elasticity and near bursting of the mother cell. Inset: The heat map bar is a measure of elasticity with lower numbers (black) representing the highest level of elasticity.

Wang, C., Stanciu, C., Ehrhardt, C.J., Yadavalli, V.K. 2015. *Journal of Microscopy* 258: 49–58

triggers the latter to remove the anti-sigma factor SpoIIAB; this liberates the RNA polymerase sigma factor (◀ Section 6.5) σ^F , a key step in the sporulation process.

Endospore Formation: Alternative Sigma Factors

Once a cell of *B. subtilis* commits to sporulation, endospore development is controlled by four different σ factors, two of which, σ^F and σ^G , activate genes needed inside the developing endospore (called the *forespore*) and two of which, σ^E and σ^K , activate genes needed in the mother cell surrounding the forespore (Figure 8.18b). The sporulation signal, transmitted via Spo0A, activates σ^F in the forespore (σ^F is already present in the forespore but is inactive because it is bound by an anti-sigma factor, Figure 8.18a). Once free, σ^F is active and can bind to RNA polymerase and promote transcription of genes whose products are needed for the next stage of sporulation (Figures 8.1a and 8.18b). These include the gene encoding the sigma factor σ^G and the genes for proteins that cross into the mother cell and activate σ^E .

Active σ^E is required for transcription of yet more genes inside the mother cell, including the gene for σ^K . The sigma factors σ^G (in the forespore) and σ^K (in the mother cell) are required for transcription of genes needed even later in the sporulation process (Figure 8.18b). Eventually, the many spore coats and other unique structures and conditions typical of the endospore (◀ Section 2.8 and Table 2.1) are formed, and the mature endospore is released.

Nutrients for Endospore Formation

Nutrient limitation is the major trigger of sporulation in *Bacillus* (◀ Section 2.8). But if this is the case, how do cells obtain sufficient nutrients to complete the formation of endospores? One fascinating aspect of the regulation of endospore formation is another regulatory event in which sporulating cells cannibalize cells of their own species. Those *Bacillus* cells in which Spo0A has already become activated secrete a toxic protein that lyses nearby *Bacillus* cells whose Spo0A protein has not yet become activated.

Figure 8.18 Control of endospore formation in *Bacillus*. After external signals for sporulation are received, a cascade of sigma (σ) factors controls differentiation. (a) Active SpoIIAA binds the anti- σ factor SpoIIAB, thus liberating the first σ factor, σ^F . (b) σ^F initiates a cascade of sigma factors, some of which already exist and need to be activated, others of which are not yet present and whose genes must be expressed. These σ factors then promote transcription of genes needed for endospore development.

This lytic protein is produced along with a second protein that functions to delay sporulation of neighboring cells. Cells committed to sporulation also make an antitoxin protein to protect themselves against the effects of their own toxic protein. When lysed, their sacrificed sister cells are used as a source of nutrients for developing endospores. Shortages of certain key nutrients, in particular phosphate, increase transcription of the gene that encodes the toxic protein.

In sporulation we thus see not only a strategy by which cellular differentiation allows the species to form cells that can withstand adverse conditions, but a strategy in which survival of a few (as opposed to all) cells of the species in a population is a priority and is facilitated by the sacrifice of other cells of the same species (see Figure 8.30 to visualize this strategy).

- What is an anti-sigma factor and how can its effect be overcome?

8.7 Regulation of Endospore Germination

Once cells have proceeded from cell to endospore, they are not committed to dormancy indefinitely. While endospores are not metabolically active and can remain dormant for years, they are still able to sense and respond to nutrients and favorable growth conditions. Such circumstances allow endospores to convert back to vegetative cells by triggering a highly ordered developmental process

called *germination*. This process essentially reverses the steps in sporulation, and in *Bacillus*, it is orchestrated by over 600 proteins and occurs in three consecutive stages: activation, germination, and outgrowth (Figure 8.19).

Triggers for Activating Endospore Germination

Although an endospore is considered to be dormant, there are receptors called *germinant receptors* (GR) within the inner membrane surrounding the core of the endospore (Figure 8.19). GRs exist in clusters called the “germinosome,” which functions to sense and bind nutrients such as amino acids, sugars, and cell wall peptides from vegetative cells. Germinants trigger stage I of endospore germination—activation. While it is unknown how specific GR binding can be, the protein GerA is known to bind the amino acid alanine, and GerB and GerK bind a mixture of asparagine, glucose, fructose, and potassium ions as germinants. Temperature increases also help trigger germination by altering endospore inner membrane properties and GR conformation, processes that lead to more efficient germinant binding.

How does binding of a germinant by a GR trigger activation of an endospore? This is not completely understood; however, it is known that a cascade of events occurs following germinant binding that results in the release of monovalent cations and calcium–dipicolinic acid (DPA, ◀ Section 2.8) from the spore core. This release is initiated by reversing sporulation factor activity (Figure 8.19), a process that allows for partial rehydration of the endospore core (the endospore core contains a small fraction of the water content of a vegetative cell, ◀ Table 2.1). Besides these physiological events, expression of genes encoding the cellular machinery for major molecular

Figure 8.19 Germination of *Bacillus* endospores. The binding of nutrients to germinant receptors triggers three stages that result in conversion of an endospore to an actively dividing vegetative cell. Photos show time-lapse images of expression of a red fluorescent protein as endospores (green) become metabolically active (red). DPA, dipicolinic acid. Images adapted from Mutlu, A., et al. 2018. *Nat. Commun.* 9: 69.

processes such as transcription and translation are increased along with those encoding chaperones for protein folding (◀ Section 6.11) necessary for the cell to enter the germination and outgrowth stages, to be considered now.

Germination and Outgrowth Stages

Once stage I is completed, the next step to spore germination is the triggering of cortex lytic enzymes (CLE) to degrade peptidoglycan in the endospore cortex (Figure 8.19). Cortex peptidoglycan is modified from normal peptidoglycan such that CLE can recognize it and not degrade cell wall peptidoglycan produced during outgrowth of vegetative cells. This removal of the endospore cortex is the major event of stage II—*germination*. Once the endospore cortex has been degraded, complete hydration is achieved and this sets the stage for more active metabolism.

During stage III of endospore germination—*outgrowth*—germinated cells begin near-normal rates of metabolism and commence events necessary to initiate the cell cycle and binary fission (Figure 8.3). Cell elongation during outgrowth results in escape of the newly emerging vegetative cell from spore coats (Figure 8.19). Outgrowth requires the increased expression of genes encoding energy-generating processes, such as the citric acid cycle and respiratory enzymes (Chapter 3). Outgrowth is also triggered by the

increased expression of genes encoding enzymes that biosynthesize peptidoglycan, teichoic and lipoteichoic acids (components of the gram-positive cell wall, ▶ Section 2.3 and Figure 2.10) and the cell division protein FtsZ (Section 8.3).

Check Your Understanding

- Where in the endospore are germinant receptors found, and what types of molecules do they detect?
- How does reversing the activity of sporulation factors lead to hydration of the endospore?
- What type of enzyme is necessary to remove the endospore cortex?

8.8 *Caulobacter* Differentiation

In addition to endospore formation in *Bacillus*, the gram-negative aquatic bacterium *Caulobacter* provides a second example of a cell that divides into two genetically identical daughter cells that are both structurally and functionally distinct and express different sets of genes.

Caulobacter is a genus of *Alphaproteobacteria* (Figure 8.11) that undergoes a simple life cycle and is a common bacterium in oligotrophic

(nutrient-poor) aquatic environments (► Section 15.18). In the *Caulobacter* life cycle, free-swimming (swarmer) cells alternate with cells that lack flagella and instead are attached to surfaces by a stalk with a holdfast at its end. The role of swarmer cells is strictly dispersal because swimmers cannot divide to form new swarmer cells nor replicate their DNA. Conversely, the role of the stalked cell is strictly reproduction. In order to divide, swarmer cells must first differentiate into stalked cells, and to swim, stalked cells must first produce swimmers; this is the nature of the *Caulobacter* life cycle (Figure 8.20; ◀ Section 7.9 and Figure 7.25b).

Regulatory Features

The *Caulobacter* cell cycle is controlled by three major regulatory proteins whose concentrations oscillate in succession. Two of these are the transcriptional regulators GcrA and CtrA. The third is DnaA, a protein that functions both in its normal role in initiating DNA replication (Section 8.2) and also as a transcriptional regulator. Each of these regulators is active at a specific stage in the cell cycle,

Figure 8.20 Cell cycle regulation in *Caulobacter*. Levels of three global regulators, CtrA, DnaA, and GcrA, oscillate through the cycle as shown. G1 and G2 are the two growth phases and S is the DNA synthesis phase. In G1 swarmer cells, CtrA represses initiation of DNA replication and expression of GcrA. At the G1/S transition, CtrA is degraded and DnaA levels rise. DnaA binds to the origin of replication and initiates replication (see inset photo). GcrA also rises and activates genes for cell division and DNA synthesis. At the S/G2 transition, CtrA levels begin to rise again and shut down GcrA expression. GcrA levels slowly decline in the stalked cell but are rapidly degraded in the swarmer (the daughter cell). CtrA is degraded in the stalked cell. Inset: Fused to the green fluorescent protein as a reporter, a subunit of DNA polymerase is localized in the end of the stalked *Caulobacter* cell where DNA replication occurs. Each cell of the dividing *Caulobacter* pair is about 2 μm long.

and each controls many other genes needed at that particular stage in the cycle.

CtrA is activated by phosphorylation by a sensor kinase (◀ Section 7.5) in response to cell cycle signals. Environmental starvation signals such as carbon and ammonia limitation also trigger the stringent response and ppGpp production (◀ Section 7.9), which prevent degradation of CtrA-P in emerging swarmer cells. Once phosphorylated, CtrA-P activates genes that encode synthesis of the flagellum and other functions specific to swarmer cells. Conversely, CtrA-P represses the synthesis of GcrA and also inhibits the initiation of DNA replication in swarmer cells by binding to and blocking the origin of replication (Figure 8.20).

As the cell cycle proceeds, CtrA is degraded by a specific protease, and as a consequence, levels of DnaA begin to rise. The absence of CtrA-P allows access to the chromosomal origin of replication, and, as in all *Bacteria*, DnaA binds to the origin and triggers the initiation of DNA replication (Section 8.2). In addition, *Caulobacter* DnaA activates several other genes needed for chromosomal replication. The level of DnaA then falls due to protease degradation, and the level of GcrA rises. The GcrA regulator promotes the elongation phase of chromosome replication, cell division events, and the growth of the stalk on the immobile daughter cell. Eventually, GcrA levels fall and CtrA reappears (in the daughter cell destined to swim away) (Figure 8.20), and the cell cycle is repeated.

Caulobacter and the Eukaryotic Cell Cycle

Both external stimuli and internal factors such as nutrient and metabolite levels coordinate the events of the *Caulobacter* cell cycle (◀ Section 7.9). Since its genome has been sequenced and good genetic transfer systems are available, the *Caulobacter* cell cycle has been used as a model for studying cell developmental processes in other organisms as well. This focus is primarily due to the strict cell cycle followed by *Caulobacter*, which resembles the cell cycle of eukaryotic cells in many respects. In fact, the resemblance is so striking that terminology used to describe the eukaryotic cell cycle has been adapted to the *Caulobacter* system (Figure 8.20).

In eukaryotic cells, phase G1 of cell division is where growth and normal metabolic events occur, and in phase G2 the cell prepares for subsequent mitotic events, which occur in the M phase. Between G1 and G2 is the S phase, where DNA replication occurs. In the *Caulobacter* life cycle there is no mitosis, of course, but analogs of the G1, G2, and S phases are apparent (Figure 8.20), making this bacterium an excellent model for studying cell-division events in higher organisms.

We now consider one other well-studied cell differentiation process, this time in a metabolically robust oxygenic phototrophic bacterium in which photosynthetic O_2 production has driven the evolution of a specialized structure for nitrogen metabolism.

Check Your Understanding

- Why are the levels of DnaA protein controlled during the *Caulobacter* cell cycle?
- When do the regulators CtrA and GcrA carry out their main roles during the *Caulobacter* life cycle?

8.9 Heterocyst Formation in *Anabaena*

Cyanobacteria are oxygenic phototrophs; that is, their photosynthetic metabolism yields oxygen (► Sections 14.6 and 15.3). They are also able to perform nitrogen fixation—the reduction of N_2 to NH_3 as a nitrogen source (◄ Section 3.12). Nitrogen fixation is a highly energy-demanding process catalyzed by *nitrogenase*, an extremely oxygen-sensitive enzyme. How then is it possible for both nitrogen fixation and oxygenic photosynthesis to occur simultaneously in the same bacterium? To solve this problem, some filamentous cyanobacteria such as *Anabaena* and *Nostoc* undergo a developmental process to form specialized cells called **heterocysts** that are dedicated to nitrogen fixation.

Heterocyst Formation

Because heterocysts lack photosystem II—the pigment–protein complex that produces O_2 during oxygenic photosynthesis (◄ Section 3.11 and ► Section 14.6)—they are anoxic cells. This anaerobic lifestyle provides a hospitable environment for nitrogenase and thus nitrogen fixation. Heterocysts arise from the differentiation of vegetative cells that contain photosystem II and thus produce O_2 , and typically develop in a regular pattern along a filament (Figure 8.21a). As we will see, this patterning separates two incompatible metabolic processes while still allowing for necessary nutrient exchanges and growth.

Heterocyst formation requires several morphological and metabolic changes that are regulated by a network of systems that sense both external conditions and intracellular signaling molecules. These changes include the formation of a thickened cell wall to prevent O_2 diffusion into the cell, inactivation of photosystem II, expression of nitrogenase, and the patterning of heterocyst differentiation along the filament (Figure 8.21a). Because nutrients can be exchanged between heterocysts and adjacent vegetative cells (Figure 8.21b), other regulatory steps are initiated to prevent nearby vegetative cells from undergoing the developmental conversion to heterocysts.

Regulation of Heterocyst Formation

The cascade of events leading to heterocyst formation is triggered by a limitation of “fixed” nitrogen (nitrate, ammonia, etc.); the limitation is sensed in the vegetative cell as an elevation in levels of α -ketoglutarate, the acceptor molecule for formation of the amino acid glutamate (◄ Section 3.14). When the cell is starved for fixed nitrogen, α -ketoglutarate accumulates and activates the transcriptional global regulator NtcA. NtcA then activates transcription of the gene *hetR*, which encodes HetR, the major transcriptional regulator controlling heterocyst formation. HetR activates a cascade of genes necessary for differentiation of the heterocyst, expression of cytochrome *c* oxidases to remove traces of O_2 that may still be present, and expression of the *nif* operon for the synthesis and regulation of nitrogenase (Figure 8.21c).

Only specific cells along the filament form heterocysts, and the consistent pattern observed (Figure 8.21a) is under strict control. Intercellular connections between cells in an *Anabaena* filament allow vegetative cells to provide fixed carbon to the heterocyst as an electron donor (for N_2 reduction by nitrogenase) in exchange for some of the NH_3 produced. However, the cell connections also allow for intercellular communication by regulatory molecules. In this regard, differentiating cells produce a small peptide called PatS that diffuses away from the developing heterocyst to form a gradient along the vegetative cells in the filament (Figure 8.21b). PatS inhibits differentiation in vegetative cells by preventing HetR from activating genes necessary for heterocyst formation. A second regulator called PatA, a response regulator analogous to the chemotaxis response regulator CheY (◄ Sections 7.5 and 7.6 and Figure 7.17), also participates in heterocyst pattern development. PatA promotes the activity of HetR, decreases the activity of PatS, and may also participate in cell division.

While other regulatory links in heterocyst formation remain active areas of study, the differentiation of vegetative cells to heterocysts in heterocystous cyanobacteria is a unique example of multicellular patterning and intercellular communication in prokaryotic cells. We

Figure 8.21 Regulation of heterocyst formation. (a) Fluorescence microscopy showing *Anabaena* filaments expressing the green fluorescent protein linked to heterocyst-specific genes; vegetative cells are red from chlorophyll *a* fluorescence. (b) Molecule dispersion in heterocysts. Fixed carbon from photosynthesis in the vegetative cells is transferred to the heterocyst, while fixed nitrogen produced in the heterocyst is shared with the vegetative cells. The protein PatS, which is synthesized by heterocysts, is also dispersed to neighboring vegetative cells where it inhibits expression of genes necessary for heterocyst formation. (c) Cascade of events in the activation of genes necessary for heterocyst formation. The cascade is initiated by an increase in levels of α -ketoglutarate, the carbon skeleton of the amino acids glutamate and glutamine.

now consider a final developmental model system, one in which cell populations—in contrast to individual cells—cooperate to dramatically change their growth characteristics.

Check Your Understanding

- Vegetative cells in *Anabaena* produce oxygen, while its heterocysts do not. Why?
- What is the major transcriptional regulator that controls heterocyst formation?

8.10 Biofilm Formation

In Section 4.9 we briefly discussed the basic characteristic of bacterial biofilms—attached polysaccharide matrices containing embedded bacterial cells—along with their environmental and medical significance. We revisit the concept of biofilms here with a focus on the molecular mechanisms that control biofilm development.

Biofilm formation can be controlled in different ways, and the process has been particularly well studied in two gram-negative *Bacteria*, *Pseudomonas aeruginosa* and *Vibrio cholerae*. However, the process is not limited to *Bacteria*, as biofilms have also been observed in some *Archaea* and yeasts. Biofilm formation can be considered a type of developmental cycle that has four basic stages: (1) attachment, (2) colonization, (3) development, and (4) dispersal. Random collision of cells with a surface accounts for the initial cell attachment, which is facilitated by cell surface structures such as flagella and pili or surface proteins. Attachment of a cell to a surface (Figure 8.22) is a signal for the expression of biofilm-specific genes. The latter include genes encoding proteins that produce intercellular signaling molecules and *extracellular polymeric substances* (abbreviated as *EPS*), which includes polysaccharide, DNA, and protein, that initiate matrix formation. Once committed to biofilm formation, a previously suspended (planktonic) cell typically loses its flagella and becomes nonmotile. However, biofilms are not static entities and cells can be released from the biofilm through an active process of dispersal.

Cyclic Di-GMP and Biofilm Formation

Several signals guide bacteria in transitioning from planktonic growth to life in a semisolid matrix. The actual switch from planktonic to biofilm growth in many bacteria is triggered by the cellular accumulation of the regulatory nucleotide *cyclic di-guanosine monophosphate* (c-di-GMP) (Figure 8.23). Although various nucleotides play important regulatory roles in all domains of life (◀ Section 7.8), c-di-GMP is widely distributed only in *Bacteria*. The synthesis or degradation of c-di-GMP depends on both environmental and cellular cues, and its synthesis either promotes or inhibits a variety of physiological events including cell differentiation, bacterial development, and biofilm-relevant functions (Figure 8.23).

Enzymes that synthesize c-di-GMP from GTP are called diguanylate cyclases, and these enzymes often possess an allosteric binding site for c-di-GMP. Thus, these enzymes are sensitive to feedback inhibition (◀ Section 7.15) and c-di-GMP production is reduced once elevated levels exist in the cell. Conversely, proteins with phosphodiesterase domains degrade the signaling nucleotide to the guanine derivatives pGpG and GMP (Figure 8.23). These two types of proteins coordinate antagonizing activities to yield cellular levels of

Attachment (adhesion of a few motile cells to a suitable solid surface)	Colonization (intercellular communication, growth, and polysaccharide formation)	Development (more growth and polysaccharide)	Active Dispersal (triggered by environmental factors such as nutrient availability)

The matrix is formed and becomes more extensive as the biofilm grows, eventually releasing cells. (b) Photomicrograph of a DAPI-stained biofilm that developed on a stainless steel pipe. Note the water channels.

c-di-GMP necessary to influence cellular activities. This regulatory molecule directly affects a host of cellular activities by binding to structural proteins and enzymes as well as to transcription factors and riboswitches (◀ Sections 7.2 and 7.13, respectively). In the specific context of biofilms, c-di-GMP binds to proteins that reduce the activity of the flagellar motor, regulates cell surface proteins required for attachment, and mediates the biosynthesis of extracellular matrix polysaccharides of the biofilm.

Pseudomonas aeruginosa and Biofilms

Pseudomonas aeruginosa can form a tenacious biofilm (◀ Section 4.9) containing specific polysaccharides that subsequently increase its pathogenicity and prevent the penetration of antibiotics. *P. aeruginosa* is a classic opportunistic pathogen and from its primary reservoir in soil can infect the blood, lungs, urinary tract, ears, skin, and other tissues of humans. The major symptoms of the human genetic disease cystic fibrosis are caused by thick biofilms of *P. aeruginosa* that develop in the lungs, and the bacterium is a significant nosocomial (hospital-acquired) pathogen.

Besides the intracellular activities triggered by c-di-GMP, intercellular communication by quorum sensing (◀ Section 7.7) is critical for the development and maintenance of *P. aeruginosa* biofilms. As

Figure 8.23 The signaling molecule cyclic di-guanosine monophosphate. This molecule is used as an intracellular signaling molecule by many bacteria to control specific physiological processes by binding to various effectors. Two molecules of GTP are converted to c-di-GMP by the activity of proteins with GGDEF (diguanylate cyclase) domains, while the activity of proteins with phosphodiesterase domains converts c-di-GMP to pGpG and GMP.

the regulatory molecules called *acyl homoserine lactones* (AHLs, ◀ Figure 7.18b) accumulate, they signal *P. aeruginosa* cells that the population of this species is enlarging and thus the opportunity for biofilm formation exists. The production of AHLs also triggers expression of a subset of the genes necessary for biofilm formation including those that increase extracellular polysaccharide and c-di-GMP synthesis.

Elevated c-di-GMP levels initiate the production of EPS, including a polysaccharide called Pel, which functions as both a primary scaffold for the microbial community and a mechanism for resisting the penetration of antibiotics; c-di-GMP also leads to decreased flagellar function. Over time in nutrient-rich conditions, *P. aeruginosa* cells can develop mushroom-shaped microcolonies that can be more than 0.1 mm high and contain millions of cells (Figure 8.22; ◀ Figure 4.16). The final architecture of a biofilm is determined by several factors in addition to signaling molecules, and these include both nutritional factors and the flow rate of the biofilm environment.

Besides the contribution of decreased flagellar movement and Pel production, DNA release by lysed cells can also promote biofilm formation in *P. aeruginosa* (Figure 8.24a). This event—termed “explosive death”—occurs in a subpopulation of *P. aeruginosa* cells. Explosive death is caused by the expression of a lysis protein encoded in the *P. aeruginosa* genome by an inactive prophage; the protein is produced in response to stress conditions such as DNA-damaging reagents and antibiotics and is occasionally a random event under normal conditions. When this lysis enzyme is expressed, the bacterial cells break open and release their DNA (Figure 8.24a). This highly viscous DNA, now extracellular, is integrated into the EPS that forms the biofilm scaffold. Besides the release of DNA, explosive death also leads to shattered cell membrane fragments that curl together to form

Figure 8.24 Explosive death and biofilm formation in *Pseudomonas aeruginosa*. This gram-negative gammaproteobacterium (▶ Section 16.4) exists in soil as a harmless saprophyte, but can also be a vicious opportunistic human pathogen that can cause infections of blood, burns, and related wounds, and ears, lungs, and eyes. *P. aeruginosa* is of particular concern in individuals suffering from the genetic disease cystic fibrosis because of the organism’s ability to form biofilms that affect lung capacity. (a) Cell lysis and DNA release. Production of the lysis enzyme causes the bacterial cells (purple) to break open, releasing their DNA (yellow). This DNA is critical to forming the EPS that holds the biofilm together. (b) Cell bursting and biofilm formation. Cell lysis leads not only to the release of DNA, but also to shattered cell membrane fragments that curl together to form vesicles surrounding proteins and DNA that contribute to EPS formation (small blue circles with red centers). Images adapted from Turnbull, L., et al. 2016. *Nat. Commun.* 7: 1120.

Turnbull, L. et al. 2016. *Nature Communications* 7: 1120

vesicles surrounding cellular proteins and DNA. These vesicles also contribute to EPS formation and biofilm development (Figure 8.24b). Explosive death likely explains why antibiotic treatment of *P. aeruginosa* infections often enhances biofilm formation; this protective mechanism in bacterial cells thwarts antibiotic penetration.

Biofilm formation strategies can differ among species of the same genus. In *Pseudomonas fluorescens*, increases in c-di-GMP also promote biofilm formation. However, the biofilm machinery regulated by c-di-GMP in *P. fluorescens* differs from that of *P. aeruginosa*. In *P. fluorescens*, changes in c-di-GMP levels affect secretion and cell surface localization of a large adhesion protein called LapA that helps attach cells to the surface. For example, when environmental levels of a key nutrient such as phosphate are *high*, c-di-GMP levels are high, LapA localizes to the cell membrane, and biofilm synthesis is promoted. However, in response to *low* levels of phosphate, *P. fluorescens* cells maintain a low c-di-GMP level that prevents localization of LapA to the outer membrane, thereby disabling the attachment mechanism required to initiate biofilm formation. If phosphate levels continue to fall within a *P. fluorescens* biofilm, the associated reduction in c-di-GMP levels results in the release of a specific protease normally sequestered by a c-di-GMP-binding protein. This protease cleaves

LapA, resulting in the release of attached cells and promoting their dispersal to explore for available nutrients in nearby habitats.

Vibrio cholerae and Biofilms

Vibrio cholerae, the causative agent of cholera (► Section 33.3), forms biofilms containing polysaccharide and the carbohydrate-binding matrix proteins RbmA, RbmC, and Bap1. Figure 8.25 illustrates the impressive production of these matrix proteins during biofilm growth. Synthesis of these biofilm proteins is controlled by both intercellular and intracellular signaling. Two transcriptional activators, VpsR and VpsT, are required to activate expression of the matrix protein genes, while a repressor protein, HapR, negatively regulates biofilm formation by decreasing the activity of the two activator proteins VpsT and VpsR. The activity of these key transcription factors is controlled by a host of other factors including two-component regulatory systems, alternative sigma factors, catabolite repression, quorum sensing, and regulatory RNAs (Chapter 7).

While c-di-GMP is the inducer molecule that activates VpsT and thus expression of genes for biofilm formation (Figure 8.23), quorum sensing in *V. cholerae* acts in an opposite manner from that in

Figure 8.25 *Vibrio cholerae* biofilm formation. (a) Time-course multiresolution fluorescence micrographs illustrating the production and release of the carbohydrate-binding matrix proteins RbmA, RbmC, and Bap1 during biofilm formation. Each protein is detected by the binding of a specific fluorescently labeled antibody. (b) Low-cell-density-dependent activation of genes encoding carbohydrate-binding matrix

proteins for biofilm formation. A low concentration of quorum-sensing molecules promotes transcription of a small regulatory RNA that binds to the mRNA encoding the HapR repressor. This results in lower levels of HapR protein and thus synthesis of the transcriptional activators VpsR and VpsT; these activate transcription of the genes *rbmA*, *rbmC*, and *bap1*. Note that VpsT is active when bound to c-di-GMP.

(c) High-cell-density-dependent inhibition of biofilm formation. A high concentration of quorum-sensing molecules results in decreased expression of the sRNA that binds to the mRNA encoding HapR. Thus, high levels of HapR protein exist in the cell, inhibiting the activity of VpsR and VpsT. This signal cascade shuts off transcription of *rbmA*, *rbmC*, and *bap1*.

P. aeruginosa. At low cell densities, small regulatory RNA molecules bind to the mRNA encoding HapR, thus preventing its translation. As *V. cholerae* cell density increases, the level of quorum signaling molecules also increases and this results in decreasing levels of the regulatory RNAs that target HapR mRNA. The latter results in an increased concentration of the HapR repressor, decreased expression of the activator proteins VpsT and VpsR, and the dispersal of attached cells. Thus, unlike in *P. aeruginosa*, in *V. cholerae*, biofilm formation is triggered by low cell densities and repressed by high cell densities. Or, said another way, in *V. cholerae*, the accumulation of quorum sensing molecules triggers a regulatory cascade that ultimately results in the repression of biofilm formation genes and the activation of flagellar genes, just the opposite of what occurs in *P. aeruginosa*.

The ecological significance of this phenomenon is that biofilm formation is more likely to occur when *V. cholerae* is found in its natural marine environment where nutrients are typically scarce, thus leading to smaller populations than those found inside the close quarters of an intestinal cell where nutrients are more plentiful. Biofilm formation allows the *V. cholerae* cell to attach to marine surfaces such as plankton (► Section 33.3), crustaceans, and sediments for greater access to nutrients and protection from perturbations. The final step in biofilm formation, dispersal, ultimately aids in the transmission of *V. cholerae* to new host cells.

Because the biofilm lifestyle of many pathogenic bacteria often leads to either persister cells (Section 8.12) or antibiotic-resistant cells (or both), and because biofilms themselves function as barriers to the penetration of antimicrobial drugs, there is great medical interest in understanding the molecular biology of biofilm development and pursuing new classes of drugs that might interfere with biofilm formation.

Biofilms and Archaea

While our understanding of biofilms in *Archaea* is just beginning, at least some of the events in archaeal biofilm formation appear to share features with those of bacterial biofilms. Most of our

knowledge comes from studying biofilm formation in the motile hyperthermophilic sulfur chemolithotroph *Sulfolobus acidocaldarius* (Figure 8.26a).

A transcription factor called AbfR1 plays a major role in the *Sulfolobus* biofilm. In the phosphorylated state, AbfR1 activates biofilm formation through the increased expression of genes for EPS and pili synthesis and decreased expression of genes encoding archaeella (◀ Section 2.9) synthesis (Figure 8.26b). This ultimately leads to increased cell attachment and decreased motility. The opposite occurs when AbfR1 is in the unphosphorylated state—archaella production is activated and pili and EPS synthesis repressed. While the signal and sensor kinase (◀ Section 7.5) responsible for phosphorylating AbfR1 remain unknown, biofilm formation in *Sulfolobus* appears to be a response to significant changes in pH or temperature.

Although the role that quorum sensing (◀ Section 7.7) may play in *Sulfolobus* biofilm formation is also unclear, *Archaea* have been shown to produce quorum-sensing-like molecules. *Archaea* do not produce c-di-GMP—a major regulator in *Bacteria* (Figure 8.23)—but genomic analysis suggests that many species can produce c-di-AMP. This regulatory molecule, which is also found in *Bacteria*, may therefore play a role in archaeal biofilm formation (Figure 8.26) and other events in *Archaea* where quorum-sensing molecules may participate.

We will continue our discussion of biofilms and strategies to control their formation when we consider the ecology of biofilms in Chapter 20. But for now, we move on to Part III where we consider antibiotics and bacterial growth and focus on the alarming practical problem of antibiotic resistance.

Check Your Understanding

- What are the four basic stages of biofilm formation?
- Besides autoinducer synthesis, what intracellular molecule promotes biofilm formation in many *Bacteria*?

Figure 8.26 Biofilm formation in the crenarchaeon *Sulfolobus acidocaldarius*. *Sulfolobus* is an acidophilic and hyperthermophilic sulfur-oxidizing archaeon (► Section 17.10). Activation and repression are dependent on the phosphorylation state of AbfR1 with green arrows indicating activation and red lines indicating repression. As can be seen, when AbfR1 is phosphorylated, motility is repressed and attachment activated. Image adapted from Koerdert, A., et al. 2010. *PLoS ONE* 5(11): e14104.

III • Antibiotics and Microbial Growth

Antibiotics target specific bacterial growth processes and have been a boon to clinical medicine. However, antibiotic efficacy has been compromised by bacterial resistance mechanisms that include mutations that alter the targets, drug destruction or efflux, and entering a transient dormant state.

Throughout this chapter we have discussed how cells coordinate their molecular biology to optimize steps in microbial growth. But what about mechanisms that short-circuit these synchronized processes? Here we focus on how antibiotics target growth processes and the bacterial responses that can lead to resistance and persistence. In Chapter 28 we will focus on the clinical significance of antibiotics and consider their spectrum of activity and spread of resistance.

8.11 Antibiotic Targets and Antibiotic Resistance

Antibiotics are antimicrobial agents produced by microorganisms, primarily certain bacteria and fungi. These agents are characterized by their ability to either kill or inhibit the growth of bacteria, and all target molecular processes in the cell that are essential to growth and survival. In this section we consider how antibiotics work and some key resistance mechanisms that bacteria have evolved to counter their effects.

Antibiotics That Target Major Molecular Processes

Because all steps within the central dogma (the flow of genetic information; Chapter 6) are essential for growth, many antibiotics specifically target enzymes that catalyze DNA replication, RNA synthesis, and protein synthesis (Figure 8.27). For example, quinolones such as ciprofloxacin target DNA gyrase in gram-negative bacteria and topoisomerase IV in gram-positive bacteria. Thus quinolones lead to cell death by interfering with DNA unwinding and replication (◀ Section 6.1). Likewise, when transcription is inhibited in a growing cell, mRNA cannot be made and new protein synthesis is interrupted. The antibiotics rifampin and actinomycin prevent RNA synthesis by either blocking the RNA polymerase active site (rifampin) or blocking RNA elongation by binding to the major groove in DNA (◀ Section 6.5).

Many antibiotics inhibit bacterial growth by targeting some aspect of protein synthesis (Figure 8.27). Recall that ribosomes in *Bacteria* are 70S structures while eukaryotic ribosomes are 80S (◀ Section 6.10). The antibiotic puromycin contains a region that mimics the 3' end of a tRNA, and this structural mimicry results in specific binding of the antibiotic to the A site in the 70S ribosome; this induces chain termination and effectively shuts down protein synthesis. Aminoglycoside antibiotics such as streptomycin specifically target the 16S rRNA of the 30S ribosome and result in the ribosome misreading mRNAs, thus leading to error-filled proteins that accumulate in the cell and ultimately inhibit growth.

Antibiotics That Target the Cell Membrane and Wall

Other common antibiotic targets include the cell membrane, the cell wall, and specific metabolic processes (Figure 8.27).

Figure 8.27 Growth targets of select antibiotics. Antibiotic targets are in red bold.

Daptomycin is a lipopeptide produced by certain *Streptomyces* species that specifically binds to phosphatidylglycerol residues of the bacterial cytoplasmic membrane (◀ Section 2.1); this leads to pore formation and depolarization of the membrane, ultimately resulting in cell death. Some antibiotics target the gram-negative cell outer membrane (◀ Section 2.4). For example, polymyxins are cyclic peptides whose long hydrophobic tails specifically target the LPS layer and ultimately disrupt membrane structure, causing leakage and cell death.

Several antibiotics target the synthesis of peptidoglycan in bacteria, including the β -lactams penicillin, cephalosporin, and their derivatives. These antibiotics inhibit growth by interfering with proteins that catalyze transpeptidation (penicillin-binding proteins, Section 8.5), the process by which cross-links are made between muramic acid residues that contribute to the structural strength of peptidoglycan (◀ Section 2.3). Similarly, the antibiotic vancomycin inhibits peptidoglycan synthesis in gram-positive bacteria by binding to the pentapeptide of peptidoglycan precursors and preventing the formation of peptide interbridges by transpeptidases. The topical antibiotic bacitracin prevents peptidoglycan synthesis by binding to the peptidoglycan precursor transport system (bactoprenol, Section 8.5) and preventing new peptidoglycan precursors from reaching the site of peptidoglycan synthesis. As autolysins continue to introduce small gaps in the existing peptidoglycan (Figure 8.16a), a shortage of precursors to patch the gaps weakens the cell wall and leads to cell lysis.

Many other antibiotics and related antimicrobials are known, some of which target other aspects of a bacterium's biology, such as particular metabolic reactions. But the bulk of clinically useful antibiotics strike one of the targets shown in Figure 8.27. We finish this section with a look at how bacteria have countered the activity of antibiotics by evolving major mechanisms of antibiotic resistance.

Antibiotic Resistance: Spontaneous Mutations and Antibiotic Modification

If bacteria are to survive the onslaught of antibiotics produced by other microbes (or their own antibiotics if they are an antibiotic-producing organism), they require resistance mechanisms of one sort or another. Resistance mechanisms are genetically encoded and fall into four classes: (1) modification of the drug target, (2) enzymatic inactivation, (3) removal from the cell via efflux pumps, and (4) metabolic bypasses (Figure 8.28).

Random chromosomal mutations can lead to antibiotic resistance. For example, spontaneous mutants of *Escherichia coli* or other bacteria resistant to the antibiotic rifampin—which inhibits the activity of RNA polymerase—can be obtained by simply exposing a large cell population to the antibiotic. Under such conditions, spontaneous mutants that produce an altered RNA polymerase unaffected by rifampin are strongly selected for.

Resistance genes can also exist on a variety of mobile genetic elements (Chapter 6), and such genes can be readily transmitted between bacteria of the same or different species by horizontal gene flow (Chapter 9). Unlike a spontaneous mutation that affects the target of the antibiotic, many of these mobile resistance genes, especially ones transmitted by R plasmids, encode enzymes that inactivate the antibiotic by altering its structure, either by chemical

modification or cleavage. As examples, β -lactamase binds to β -lactam antibiotics and cleaves a key ring structure in the molecule, and an acetylating enzyme adds acetyl groups to free hydroxy groups of chloramphenicol; once cleaved or chemically modified, the drugs can no longer bind to their target and microbial growth can continue.

Antibiotic Resistance: Efflux Pumps and Metabolic Bypasses

Another effective resistance strategy is to pump out antibiotics that have entered the cell. *Efflux pumps* are ubiquitous in gram-negative bacteria and function by transporting various molecules, including antibiotics, out of the cell (Figure 8.28). Efflux lowers the intracellular concentration of an antibiotic and thus allows the cell to survive at higher external concentrations. Many efflux pumps act promiscuously by transporting different classes of antibiotics outside of the cell, which contributes to the problem of multidrug resistance. The AcrAB-TolC efflux system of *E. coli* is one of the best-characterized efflux pumps and can pump out several antibiotics including rifampin, chloramphenicol, and fluoroquinolones (Figure 8.28, inset).

Growth as a biofilm (Section 8.10) leads to increased antibiotic resistance, a characteristic that makes infections caused by biofilm-forming bacteria difficult to treat. Although the exopolysaccharide matrix of a biofilm decreases the permeability of antibiotics, efflux pumps also play a major role. For example, genes encoding the AcrAB-TolC efflux pump in *E. coli* are upregulated when cells enter a biofilm growth mode. *Pseudomonas aeruginosa*, a classic biofilm former, encodes several multidrug efflux pumps that are also more active when cells grow in an attached state.

A final form of antibiotic resistance occurs when the target of the antibiotic is no longer essential to the cell's metabolism or survival. A classic example of this is *methicillin-resistant Staphylococcus aureus* (MRSA), the causative agent of a variety of serious, even life-threatening, infections (► Section 31.9). Methicillin is a β -lactam antibiotic that, like other penicillins, targets the activity of penicillin-binding proteins. However, unlike many penicillin derivatives, methicillin is resistant to cleavage by β -lactamase. Although many strains of *S. aureus* are killed by methicillin, MRSA strains contain a 20- to 60-kilobase DNA chromosomal (or genomic) island (► Section 13.10) called the *Staphylococcus chromosomal cassette for methicillin resistance* (SCCmec); these genes encode an *alternative* penicillin-binding protein called MecA that is not recognized by methicillin or other β -lactams (Figure 8.28).

Interestingly, MRSA strains synthesize MecA *only* in the presence of methicillin or other β -lactams. This regulation is due to the presence of the repressor protein MecI and the β -lactam sensor MecR1. In the absence of a β -lactam antibiotic, MecI binds to the operator site (◄ Section 7.2) of *mecA* and represses transcription. If the cell is treated with methicillin or other β -lactams, it triggers the MecR1 protease to degrade the MecI repressor. This induces transcription of *mecA* (and thus the production of MecA), which allows MRSA strains to synthesize peptidoglycan in the presence of methicillin. The chromosomal island of MRSA strains also possesses a transposable element (◄ Section 6.2) that encodes resistance to the antibiotics erythromycin and spectinomycin. The island is thus likely subject

Figure 8.28 Mechanisms of antibiotic resistance. Penicillin (a β -lactam antibiotic) is used to illustrate the mechanisms of modified target (modified porins), drug inactivation (β -lactamase), efflux pump, and metabolic bypass (alternative penicillin-binding protein). Genes for efflux pumps and β -lactamase enzymes can be plasmid or chromosomally encoded, while the alternative penicillin-binding protein is encoded only on the chromosome. PBP: Penicillin-binding protein. Mechanisms of antibiotic resistance are in green bold. Insert: Electron micrograph of the AcrAB-TolC efflux system from *Escherichia coli* positioned in an illustration of a gram-negative cell envelope.

to horizontal transfer to confer multidrug resistance. This reality makes MRSA a serious problem for clinical medicine.

Check Your Understanding

- Describe two targets of antibiotics and discuss why the drugs are effective.
- Some antibiotics target peptidoglycan synthesis. What is a molecular growth target of an antibiotic that inhibits peptidoglycan synthesis?
- Why are efflux pumps capable of conferring multidrug resistance?

8.12 Persistence and Dormancy

Besides being *sensitive* or *resistant* to antibiotics, a third growth response is possible—**persistence**. Persistence occurs when a population of antibiotic-sensitive bacteria produces rare cells that *transiently* become tolerant to multiple antibiotics (Figure 8.29a). These *persisters*, as they are called, are genetically identical to their antibiotic-susceptible siblings, and thus persistence is not inheritable or conferred by genetic transfer. Instead, persisters, which form at a rate of 10^{-6} to 10^{-4} in exponentially growing cultures, derive from a state of *dormancy* in which the cells are viable but do not grow.

Because antibiotics target active processes, the dormant state prevents the antibiotic from killing the cell. When antibiotic treatment is stopped, the dormant cells emerge from dormancy and grow. Persistence is believed to be the cause of recurring infections of *Mycobacterium tuberculosis* in those with chronic tuberculosis (► Section 31.4) and of *Pseudomonas aeruginosa* in those suffering from the genetic disease cystic fibrosis.

How does a subpopulation of cells go dormant while genetically identical daughter cells do not? For a cell to become a persister and be able to later reverse the process, coordinated molecular events that affect cell growth must take place. The keys to this unusual phenomenon are chromosomally encoded toxin–antitoxin modules, the stringent response (◀ Section 7.9), and a phenomenon called *phenotypic heterogeneity*. Sporulation is a classic example of cells in a population displaying different phenotypes (Section 8.6). This phenotypic heterogeneity occurs because gene expression is not equal in all cells of a population. As Figure 8.30 illustrates, a subpopulation of vegetative cells remains metabolically active after other cells have committed to forming endospores.

Toxin–Antitoxin Modules

Toxin–antitoxin (TA) modules are genes that encode two components: a toxin whose production inhibits cell growth and an antitoxin that counteracts the activity of the toxin. TA modules are found in almost all *Bacteria* and in many *Archaea*. The identification of over 30 TA systems in *Escherichia coli* and 60 TA systems in *M. tuberculosis* suggests that TA modules play a role not only in normal physiology but also in pathogenicity. It is thought that toxin activity promotes cellular adaptation to ever-changing environments by slowing down cell growth to help ensure survival during stressful conditions.

The *hipAB* genes encode a TA module that has been shown to trigger persistence in *E. coli* (Figure 8.29b). In this module, HipA is a toxin that inhibits translation and HipB is an antitoxin that is susceptible to a protease called Lon. Under normal cellular conditions, the HipA toxin and HipB antitoxin form a stable complex that prevents HipA from exerting its toxicity. However, if Lon is activated by its signal molecule polyphosphate (PolyP), the HipB antitoxin is degraded.

Figure 8.29 Persistence and the HipAB toxin–antitoxin module. (a) Antibiotic selection of persister cells and recovery from dormancy. (b) HipAB toxin–antitoxin module. During normal conditions, HipB sequesters the toxin HipA. The presence of Lon–PolyP leads to inactivation of the HipB antitoxin and free HipA toxin. HipA leads to slow growth and persistence and positively regulates the *hipAB* operon. (c) Mechanism of HipA toxin. HipA phosphorylates GltX, preventing the tRNA synthetase from charging amino acids. This leads to an uncharged tRNA entering the A site of the ribosome and the stimulation of RelA to produce (p)ppGpp.

Figure 8.30 Phenotypic heterogeneity during sporulation. Fluorescence micrograph illustrating a population of *Bacillus subtilis* cells with some members committing to developing spores, while other cells remain vegetative and metabolically active. Cells yellow or green in color are sporulating cells expressing GFP linked to a promoter for the sporulation factor Spo0A (Figure 8.18) (developing endospores are green). Cells red in color are vegetative cells expressing a red fluorescent protein linked to tryptophan synthesis genes.

Without the HipB antitoxin present to neutralize the HipA toxin, translation is inhibited and cell growth is arrested (Figure 8.29b).

How does the HipA toxin inhibit translation? HipA acts as a kinase (phosphorylating protein) targeting glutamyl-tRNA synthetase (GltX). If HipA is free to phosphorylate GltX, GltX can no longer charge its respective tRNAs with glutamine. This leads to uncharged tRNAs entering the A site of the ribosome (◀ Section 6.10) and ultimately to stalling of the ribosome and activation of RelA (Figure 8.29c). Stalling, in turn, inhibits translation and thus protein synthesis. Free HipA also binds upstream of the *hipAB* operon, further activating transcription and thus increasing the concentration of cellular HipA (Figure 8.29b).

Steps to Dormancy

As we have seen, free HipA induces ribosome stalling. This stalling not only inhibits translation but also leads to the most important criteria

for the development of persistence—production of the alarmone (p)ppGpp (guanosine tetraphosphate and guanosine pentaphosphate) by RelA and induction of the *stringent response pathway* (Figure 8.29c).

Recall that the stringent response leads to decreased rRNA and tRNA synthesis, and thus protein synthesis is inhibited (◀ Section 7.9). The pathway also leads to decreased DNA replication and cell division. Thus, those cells in a population that have triggered the stringent response no longer actively grow; they enter a state of dormancy. Although this cascade of events only occurs in a small subpopulation of cells, antibiotic treatment strongly selects and enriches for multidrug-tolerant persister cells. Once the antibiotic exposure has ended, the persisters can exit the stringent response pathway and resume producing antitoxin to neutralize the effect of the toxin. When this happens, protein synthesis returns to normal levels, allowing cells to grow.

Why does this cascade of events only occur in a *subpopulation* of cells without any sort of genetic direction? HipA-induced persistence occurs in cells that randomly produce higher amounts of the signal molecule PolyP. While it is often assumed that cells within a clonal population are homogeneous, cell-to-cell differences in gene expression and in metabolite and protein content do occur, resulting in phenotypic heterogeneity (Figure 8.30). These differences can be the result of RNA polymerase producing a subset of mRNAs through random interactions with DNA or of unequal distribution of macromolecules between daughter cells during cell division. These cell-to-cell variations can have many outcomes, but a major one for clinical medicine is the persistence of difficult-to-eradicate pathogenic bacteria whose dormant state can falsely signal a cure, only to be followed by reinfection by the same pathogen at a later date.

We move on now to a new chapter, one whose focus is on genetics and the mechanisms for genetic exchange that *Bacteria* and *Archaea* have exploited to rapidly obtain new metabolic and other properties that boost their chances of survival and reproduction.

Check Your Understanding

- Is persistence a heritable trait?
- What prevents the toxin component of TA modules from killing the cell under normal conditions?
- What occurs in the cell that results in freed HipA toxin?

Go to **Mastering Microbiology** for videos, animations, practice tests, and more.

CHAPTER REVIEW

I • Bacterial Cell Division

- 8.1** Macromolecules such as proteins and nucleic acids can be visualized in living cells using fluorescent tagging and microscopy techniques. Super-resolution microscopy can even resolve two individual molecules, generate 3D images, and track the movement of molecules throughout the cell.

Q What type of probes must be used for super-resolution microscopy and why?

- 8.2** Before cell division occurs in prokaryotic cells, two complete copies of the genome must be present. While multiple replication forks can exist to decrease generation times, the process must be regulated. The nucleoid must also segregate to the poles of the cell to allow the septum to form.

Q What is the role of PopZ in segregating the *Caulobacter* daughter chromosomes?

- 8.3** Cell division and chromosome replication are coordinately regulated, and the Fts proteins are keys to these processes. With the help of MinE, FtsZ defines the cell-division plane and helps assemble the divisome, the protein complex that orchestrates cell division.

Q What is the role of the penicillin-binding protein FtsI in cell division?

- 8.4** MreB helps define cell shape, and in rod-shaped cells, MreB forms patchlike filaments that direct cell wall synthesis along the long axis of the cell. The protein crescentin plays an analogous role in *Caulobacter*, leading to formation of a curved cell. The eukaryotic cell proteins actin and tubulin that affect shape and cell division have prokaryotic cell counterparts.

Q How does a rod-shaped bacterial cell differ morphologically if its MreB function is disrupted?

- 8.5** During bacterial growth, new cell peptidoglycan is synthesized by the insertion of peptidoglycan precursors into the preexisting peptidoglycan fabric. Bactoprenol facilitates transport of these units through the cytoplasmic membrane. Transpeptidation completes the process of cell wall synthesis by cross-linking adjacent ribbons of peptidoglycan at muramic acid residues.

Q What step is necessary prior to inserting a new peptidoglycan subunit into a growing cell wall?

II • Regulation of Development in Model *Bacteria*

- 8.6** Sporulation in *Bacillus* during adverse conditions is triggered by a complex phosphotransfer relay system that monitors multiple aspects of the environment. The sporulation factor Spo0A then sets in motion a cascade of regulatory responses under the control of several alternative sigma factors.

Q What is a common trigger for sporulation in *Bacillus*?

- 8.7** Endospore germination occurs when nutrients become available. This developmental process occurs in three stages: activation, germination, and outgrowth. Activation is triggered by nutrients binding to germinant receptors within the endospore. This binding triggers a cascade of events that ultimately leads to rehydration of the endospore, normal metabolism, growth, and cell division.

Q What type of genes are upregulated during the different stages of endospore germination?

- 8.8** Differentiation in *Caulobacter* consists of the alternation between motile cells and those that are attached to surfaces. Three major regulatory proteins—CtrA, GcrA, and DnaA—act in succession to control the three phases of the cell cycle. Each in turn controls many other genes needed at specific times in the cell cycle.

Q How is the *Caulobacter* life cycle similar to the eukaryotic cell cycle?

- 8.9** Heterocyst formation requires expression of the major regulatory protein HetR in the protoheterocysts. However, the protein must be inactivated in vegetative cells by diffusion of the PatS peptide along the filament.

Q What is meant by “patterning” during heterocyst formation?

- 8.10** During biofilm formation, cells make contact with a surface using cell structures such as flagella and pili. Once cells are attached to a surface, both intra- and intercellular signaling molecules lead to the production of an extracellular matrix and colonization. Biofilms are not static entities, and the final step in their development is dispersal and release of cells.

Q What are the regulatory roles of c-di-GMP in biofilm formation?

III • Antibiotics and Microbial Growth

- 8.11** Antibiotics are antimicrobial agents produced by microorganisms that target processes critical for growth such as DNA replication, transcription, protein synthesis, and cell wall synthesis. Specific mechanisms of antibiotic resistance include modification of the drug target, enzymatic inactivation, removal via efflux pumps, and metabolic bypass. These mechanisms are either chromosomally or plasmid encoded.

Q Why do antibiotics that target bacterial ribosomes not make humans sick?

- 8.12** Persistence is a dormant growth state in which cells are not susceptible to antibiotics. This lack of sensitivity is transient and thus not considered antibiotic resistance. Persistence is the result of toxin–antitoxin modules and the induction of the stringent response. Cells in the persistent state can resume growth once antibiotic exposure ceases.

Q What are the steps to inducing the stringent response during the development of persistence?

APPLICATION QUESTIONS

1. If DnaA was not regulated in *Escherichia coli* and multiple rounds of replication were completed before cell division, what would be the consequence to the daughter cell and why? Would the resulting cell still be considered haploid?
2. Explain how cells exhibiting different phenotypes under the same conditions can possess the same genotype. Give examples in your explanation.
3. Describe how you would genetically design a “superbug” resistant to β -lactams, methicillin, streptomycin, daptomycin, and trimethoprim.
4. Discuss why so many different sigma factors can be produced by bacteria such as *Bacillus*.

CHAPTER GLOSSARY

Antibiotic a chemical substance produced by a microorganism that kills or inhibits the growth of another microorganism

FtsZ a protein that forms a ring at the future site of septum formation in a prokaryotic cell

Green fluorescent protein (GFP) a protein that fluoresces green and is widely used in genetic analysis

Heterocysts specialized cells dedicated to nitrogen fixation

Persistence a dormant growth state in which a few members of a genetically identical population are transiently tolerant to multiple antibiotics

Reporter gene a gene used in genetic analysis because the product it encodes is easy to detect

Super-resolution microscopy a form of light microscopy that employs special fluorescent molecules to resolve structures as small as 5–50 nm

Toxin–antitoxin (TA) module a genetic locus encoding a toxin that inhibits growth and an antitoxin that neutralizes the activity of the toxin

Genetics of *Bacteria* and *Archaea* 9

MICROBIOLOGYNOW

Live Cell Imaging Captures Bacterial Promiscuity

While often considered asexual, both *Bacteria* and *Archaea* evolve quickly through DNA exchange by horizontal transfer. Increased fitness resulting from genetic promiscuity has traditionally been monitored in the laboratory through changes in physiology. However, advances in microscopy and fluorescent labeling now make it possible to witness DNA exchange using live cell imaging.

One fascinating example is the DNA uptake system (natural competence) in the bacterium *Vibrio cholerae*. Using an appendage called a pilus, *V. cholerae* is able to reach outside of its cell, snatch pieces of free DNA, and transport them into the cell. Thus, its pili effectively function as “harpoons” fishing for free DNA. The top panel of the images shown here is a time series of the “harpoon” (white arrow) being cast from the cell into the environment, attaching to free DNA (red), and then retracting back to the cell.¹

Transfer of antibiotic resistance can also be monitored using live cell imaging. The photo at the bottom shows a mixed population of *Escherichia coli* cells surrounded by the antibiotic tetracycline (labeled green). Cells possessing a

plasmid encoding resistance to tetracycline appear red due to the labeled TetA resistance protein, whereas cells sensitive to tetracycline appear green due to their uptake of the labeled antibiotic.² Why are the sensitive cells still alive? Remarkably, an efflux pump (Chapter 8) helps the sensitive cells buy just enough time to obtain the plasmid from their resistant neighbors through a genetic event called conjugation. How long does this whole process take? Transfer of the plasmid only takes minutes, and sensitive cells can express TetA in under 2 hours.

These examples highlight the astounding power of horizontal gene transfer in prokaryotic cells as well as the variety of tools at their disposal to improve their fitness. Bacterial genetics is indeed an exciting and dynamic discipline and has given birth to many of the genetic concepts we know today.

The diversity and amazing ability of bacteria to survive ever-changing environmental conditions and a host of stressors is controlled by their genetic makeup. While their asexual reproduction would suggest that cells within *Bacteria* and *Archaea* do not exchange genes, the microbiologist Joshua Lederberg made a groundbreaking discovery in 1946—like plants and animals, bacteria can also exchange genes! Lederberg's groundbreaking work showcasing genetic recombination in *Bacteria* not only earned him a Nobel Prize but also helped launch the field of molecular biology and the use of *Bacteria* to study how genes work in higher organisms, such as plants and animals.

Understanding the varied mechanisms by which *Bacteria* and *Archaea* exchange genes has helped tackle the conundrum of how these microbes can exhibit so much diversity and persist in habitats where other forms of life cannot. Gene exchange between microbes, along with genetic innovations that arise from random changes in a cell's genetic blueprint, occur frequently and confer selectable advantages that ultimately drive cell survival and genetic diversity.

In this chapter we discuss the major themes of bacterial and archaeal genetics and the processes of gene transfer from one cell to another (**Figure 9.1**). We first describe how changes arise in the genome, which can be due to random errors in DNA replication or from DNA damage, and then we consider how **horizontal gene transfer** (Figure 9.1; see also the photomicrograph of actual gene transfer on page 297) moves genes from one cell to another by mechanisms uncoupled from reproduction. Microbiologists have leveraged aspects of these mutational and genetic exchange processes to identify genes encoding exciting microbial processes such as chemotaxis, quorum sensing, and persistence that we discussed in Chapters 7 and 8. While changes to the genome underlie microbial diversity and habitat adaptation, microorganisms also possess mechanisms to maintain genomic stability, and we end this chapter by considering these. Taken together, both genomic change and genomic stability are important to the evolution of an organism and its competitive success in nature.

Figure 9.1 Overview of bacterial and archaeal genetics. DNA mutations and mechanisms of DNA transfer contribute to the genetic diversity of *Bacteria* and *Archaea*. Transduction, transformation, and conjugation are the three known ways by which prokaryotic cells can exchange genes.

I • Mutation

Changes in the human world can be good, bad, or indifferent, and the same is true of the microbial world. Changes in the genetic blueprint of a microbe may fuel its evolutionary progress, accelerate its death, or have no detectable effect on its biology.

All organisms contain a specific sequence of nucleotides in their genome, their genetic blueprint. A **mutation** is a *heritable* change in the base sequence of that genome, that is, a change that is passed from the mother cell to progeny cells. Mutations can lead to changes in the properties of an organism; some mutations are beneficial, some are detrimental, but most are neutral and have no effect. Although the rate of spontaneous mutation is low (Section 9.3), the impressive characteristic of exponential growth in *Bacteria* and *Archaea* ensures that mutations accumulate in a population surprisingly fast. Moreover, whereas a single mutation typically brings about only a small change in a cell, horizontal gene transfer often generates much larger changes. Taken together, mutation and genetic exchange fuel the evolutionary process.

We begin by considering the molecular mechanism of mutation and the properties of mutant microorganisms.

9.1 Mutations and Mutants

In order to appreciate the impact that genome changes can have on a cell (or a virus), we start with a brief genetics primer. The genomes of cells consist of double-stranded DNA. In viruses, by contrast, the genome may consist of double- or single-stranded DNA or RNA, depending on the virus (Chapters 5 and 11). By convention, a strain of an organism or a virus isolated from nature is called the **wild-type strain** and therefore contains the wild-type genome. A cell or virus derived from the wild type whose genome carries a change in nucleotide sequence is called a **mutant**. A mutant by definition differs from the wild-type strain in its **genotype**, the

nucleotide sequence of its genome (Figure 9.2a). In addition, the observable properties of a mutant—its **phenotype**—may also be altered relative to its parent (Figure 9.2b). This altered phenotype is called a *mutant phenotype*.

The term “wild type” may be used to refer to an entire organism or just to the status of a particular gene that is under investigation. Mutant derivatives can be obtained either directly from a wild-type strain or from another strain—referred to as a *parental strain*—previously derived from the wild type; for example, another mutant. Figure 9.2b shows a plate of MacConkey agar (a culture medium that contains a pH indicator that turns red if sugar is fermented) containing the sugar maltose. This medium shows the phenotypic difference between wild-type *Escherichia coli* and mutant derivatives in the maltose utilization pathway.

Depending on the mutation, a mutant strain may or may not differ in phenotype from its parent. By convention in bacterial genetics, the *genotype* of an organism is designated by three lowercase letters followed by a capital letter (all in italics) indicating a particular gene. For example, the *hisC* gene of *E. coli* encodes a protein called HisC that functions in biosynthesis of the amino acid histidine (◀ Figure 6.27). Mutations in the *hisC* gene would be designated as *hisC1*, *hisC2*, and so on, the numbers referring to the order of isolation of the mutant strains. Each *hisC* mutation would be different, and each *hisC* mutation might affect the HisC protein in different ways.

The *phenotype* of an organism is designated by a capital letter followed by two lowercase letters, with either a plus or a minus superscript to indicate the presence or absence of that property. For example, a *His⁺* strain of *E. coli* is one that is capable of making its own histidine, whereas a *His⁻* strain is not. The *His⁻* strain would therefore require a histidine supplement for growth. A mutation in the *hisC* gene leads to a *His⁻* phenotype if it eliminates the function of the HisC protein. Likewise, the *lamB* and *malQ* mutations in Figure 9.2 lead to a *Mal⁻* phenotype, as the mutants can no longer use maltose as an energy source.

Figure 9.2 Wild-type versus mutant phenotype. (a) Genotype maps of *Escherichia coli* wild-type and maltose utilization mutants; *P* is the promoter region and *mal* and *lam* regions are structural genes. (b) Growth of wild-type *E. coli* and mutants on a plate of MacConkey agar, a differential medium. The medium contains maltose as the carbon source and a pH indicator that turns red if maltose is fermented. While the wild-type strain ferments maltose, mutant strains M1 and M2 are unable to ferment maltose due to a deletion of the *lamB* gene and a point mutation in the *malQ* gene, respectively.

Isolation of Mutants: Screening versus Selection

Virtually any characteristic of an organism can be changed by mutation. Some mutations are *selectable*, conferring some type of advantage on organisms possessing them, whereas others are nonselectable, even though they may lead to a very clear change in the phenotype of an organism. A selectable mutation confers a clear advantage on the mutant strain under certain environmental conditions, so the progeny of the mutant cell are able to grow and replace the parent. A good example of a selectable mutation is drug resistance: An antibiotic-resistant mutant can grow in the presence of an antibiotic that inhibits or kills the parent (Figure 9.3a) and is thus selected under these conditions. It is relatively easy to detect and isolate selectable mutants by choosing the appropriate environmental conditions. **Selection** is therefore an extremely powerful genetic tool, allowing the isolation of a single mutant from a population containing millions or even billions of parental cells.

Some examples of important *nonselectable* mutations are secondary metabolite production loss in an antibiotic-producing organism, loss of attachment ability in a biofilm-forming organism, and loss of color in a pigmented organism (Figure 9.3b, c). All three types of mutants usually have neither an advantage nor a disadvantage over their parent cells when grown in the laboratory, although antibiotic production (► Section 16.12), biofilm formation (◄ Sections 4.9 and 8.10, and ► Section 20.4), and

pigmentation (for example, of phototrophic organisms) may have a selective advantage in nature. We can detect nonselectable mutations only by examining large numbers of colonies and looking for the “different” ones, an often laborious process called **screening**.

As illustrated in Figure 9.2 (see also Figure 9.35), a thorough understanding of microbial physiology is the key to designing successful genetic screens for nonselectable mutations. In Figure 9.2b a genetic screen for Mal^- mutants utilizes a culture medium containing a pH indicator that turns red if maltose is fermented (MacConkey agar). Because the Mal^- mutants are unable to utilize maltose, they are unpigmented compared to the red wild-type strain. To identify mutants in biofilm formation, individual colonies can be grown in liquid medium in a microtiter plate and a stain can be used to track whether cells can form a biofilm and adhere to the microtiter plate (see Figure 9.35). If possible, selection is almost always the preferred strategy over screening for obtaining mutants in a genetic experiment because selective conditions typically place such severe restraints on the population that mutants are easily detectable. Examples of common classes of mutants and the means by which they are detected are listed in Table 9.1.

Isolation of Nutritional Auxotrophs

Although screening is more tedious than selection, useful methods have been developed for screening large numbers of colonies for certain types of mutations. For instance, nutritionally defective mutants can be detected by the technique of *replica plating* (Figure 9.4). A colony from a master plate can be transferred onto an agar plate lacking the nutrient by using a sterile loop, toothpick, or even a robotic arm. Parental colonies will grow normally, whereas those of the mutant will not. Thus, the inability of a colony to grow on a medium lacking the nutrient signals that it is a mutant. The colony on the master plate corresponding to the vacant spot on the replica plate can then be picked, purified, and characterized.

A mutant strain with an additional nutritional requirement above that of the wild type or parental strain from which it was derived is called an **auxotroph** (Table 9.1), and the strain from which an auxotroph originates is called a *prototroph*. For instance, mutants of *E. coli* with His^- and Mal^- (Figure 9.2) phenotypes are histidine and maltose auxotrophs, respectively, while the parental His^+ and Mal^+ strains from which the auxotrophs were derived are the prototrophs of such strains. As described earlier, many different mutations can lead to a strain showing a His^- or Mal^- phenotype, and thus an initial step in characterizing the genetics of a metabolic pathway (such as histidine biosynthesis and maltose catabolism) would be the isolation of several His^- or Mal^- strains followed by their comparative genetic analyses (Figure 9.2). This comparative analysis process, called *complementation*, is discussed in Section 9.5.

Figure 9.3 Selectable and nonselectable mutations. (a) Development of antibiotic-resistant mutants, a type of easily selectable mutation, within the inhibition zone of an antibiotic assay disk. (b) Nonselectable mutations. UV-radiation-induced nonpigmented mutants of *Serratia marcescens*. The wild type has a dark red pigment. The white or colorless mutants make no pigment. (c) Colonies of mutants of a species of *Halobacterium*, a member of the *Archaea*. The lower pink wild-type colony contains intracellular gas vesicle nanoparticles that regulate buoyancy and also scatter light, resulting in a milky appearance. The upper red-orange colony is a mutant lacking gas vesicles and is translucent as a result.

- How does an auxotroph differ from a prototroph?

TABLE 9.1 Some examples of mutants

Phenotype	Nature of change	Detection of mutant
Auxotroph	Loss of enzyme in biosynthetic pathway	Inability to grow on medium lacking the nutrient
Temperature-sensitive	Alteration of an essential protein so it is more heat-sensitive	Inability to grow at a high temperature that normally supports growth
Cold-sensitive	Alteration of an essential protein so it is inactivated at low temperature	Inability to grow at a low temperature that normally supports growth
Drug-resistant	Detoxification of drug or alteration of drug target or permeability to drug	Growth on medium containing a normally inhibitory concentration of the drug
Rough colony	Loss or change in lipopolysaccharide layer	Granular, irregular colonies instead of smooth, glistening colonies
Nonencapsulated	Loss or modification of surface capsule	Small, rough colonies instead of larger, smooth colonies
Nonmotile	Loss of flagella or nonfunctional flagella	Compact instead of flat, spreading colonies; lack of motility by microscopy
Pigmentless	Loss of enzyme in biosynthetic pathway leading to loss of one or more pigments	Presence of different color or lack of color
Sugar fermentation	Loss of enzyme in degradative pathway	Lack of color change on agar containing sugar and a pH indicator
Virus-resistant	Loss of virus receptor	Growth in presence of large amounts of virus

9.2 Molecular Basis of Mutation

Mutations can be either spontaneous or induced events. **Spontaneous mutations** are those that occur without external intervention, and most result from occasional errors in the pairing of bases by DNA polymerase during DNA replication (Chapter 6). **Induced mutations**, by contrast, are those caused by environmental

agents and include mutations made deliberately by humans. Induced mutations can result from exposure to natural radiation (cosmic rays and so on) that alters the structure of bases in the DNA, or from a variety of chemicals that chemically modify DNA (Section 9.4).

Mutations that change only one base pair are called **point mutations** and occur when a single base-pair *substitution* occurs in

Figure 9.4 Screening for nutritional auxotrophs. The replica-plating method can be used for the detection of nutritional mutants. Colonies from the master plate are transferred using a sterile toothpick to a gridded plate containing different media for selection. The colonies not appearing on the selective medium are labeled as auxotrophs. The selective medium lacked one nutrient (the amino acid leucine) present in the master plate. Therefore, the colonies on the complete medium plate that are not represented on the selective medium plate are leucine auxotrophs (Leu^-).

the DNA. Many point mutations do not actually cause any phenotypic change (although the organism's genotype has changed). However, as for all mutations, any phenotypic change that results from a point mutation depends on exactly where in the genome the mutation occurs and the nature of the nucleotide change, as we will see.

Base-Pair Substitutions: Missense, Nonsense, and Silent Mutations

If a point mutation is within the region of a gene that encodes a polypeptide, any change in the phenotype of the cell is most likely the result of a change in the amino acid sequence of that polypeptide. The error in the DNA is transcribed into mRNA, and the erroneous mRNA in turn is translated to yield a polypeptide. In interpreting the results of a mutation, we must first recall that the genetic code is *degenerate* (◀ Section 6.9 and Table 6.4). Consequently, not all mutations in the base sequence encoding a polypeptide will change the polypeptide sequence. This is illustrated in Figure 9.5, which shows several possible results when the DNA that encodes a single tyrosine codon in a polypeptide is mutated. First, a change in the RNA from UAC to UAU would have no apparent effect because UAU is also a tyrosine codon. Although they do not affect the sequence of the encoded polypeptide, such changes in the DNA are considered one type of **silent mutation**, that is, a mutation that does not affect the phenotype of the cell. Note that silent mutations in coding regions are almost always in the *third base* of the codon (arginine and leucine can also have silent mutations in the first position) because of genetic code degeneracy.

Changes in the first or second base of the codon more often lead to significant changes in the amino acid sequence of the polypeptide. For instance, a single base change from UAC to AAC (Figure 9.5)

Figure 9.5 Possible effects of base-pair substitution in a gene encoding a protein. Three different protein products are possible from changes in the DNA for a single codon. The possible phenotypes are wild type and strains harboring missense, nonsense, or silent mutations.

results in an amino acid change within the polypeptide from tyrosine to asparagine at a specific site. This is called a **missense mutation** because the informational “sense” (the precise sequence of amino acids) in the polypeptide has changed. If the change is at a critical location in the polypeptide chain, the protein could be inactive, have reduced activity, or have modified activity. However, not all missense mutations lead to nonfunctional proteins. The outcome depends on where the substitution lies in the polypeptide chain and on how it affects protein folding and activity. While mutations in the active site of an enzyme are more likely to destroy catalytic activity than mutations in other regions of the protein, some active site mutations can alter an enzyme's substrate specificity. This type of change can result in a mutant enzyme with differing activity from the wild-type enzyme, and such events have contributed to the spectacular metabolic diversity we see in the microbial world (Chapters 3 and 14).

Another possible outcome of a base-pair substitution is the formation of a stop (nonsense) codon in the DNA. This results in premature termination of translation, leading to an incomplete polypeptide (Figure 9.5). Mutations of this type are called **nonsense mutations** because the change is from a sense (coding) codon to a nonsense (stop) codon (◀ Table 6.4). Unless the nonsense mutation is very near the end of the gene, the product is incompletely made; such truncated proteins are either inactive or, at the very least, lack normal activity.

Other terms are occasionally used in microbial genetics to describe the precise type of base substitution in a point mutation. **Transitions** are mutations in which one purine base (A or G) is substituted for another purine, or one pyrimidine base (C or T) is substituted for another pyrimidine. **Transversions** are point mutations in which a purine base is substituted for a pyrimidine base, or vice versa.

Frameshifts and Other Insertions or Deletions

Because the genetic code is read from one end of the nucleic acid in consecutive blocks of three bases (codons), any deletion or insertion of a single base pair results in a shift in the reading frame. These **frameshift mutations** often have serious consequences. Single base insertions or deletions change the primary sequence of the encoded polypeptide, typically in a major way (Figure 9.6). Such microinsertions or microdeletions can result from DNA polymerase replication errors. Insertion or deletion of two base pairs also causes a frameshift. However, insertion or deletion of three base pairs does not cause a frameshift but does add or remove a codon; this results in the addition or deletion of a single amino acid in the polypeptide sequence. Although an amino acid addition or deletion may well be deleterious to protein function, it is usually not as serious a problem as a frameshift, which scrambles the entire polypeptide sequence downstream of the mutation.

Insertions or deletions can also result in the gain or loss of hundreds or even thousands of base pairs. Such changes inevitably result in complete loss of gene function. Some deletions are so large that they may include several genes. If any of the deleted genes are essential, the mutation will be lethal. Such deletions cannot be restored through further mutations, but only through genetic recombination (Sections 9.5–9.11). Large insertions and deletions may arise as a

Figure 9.6 Shifts in the reading frame of mRNA caused by insertions or deletions. The reading frame in mRNA is established by properly positioning the message on the ribosome. The mRNA is read beginning at the 5' end (toward the left in the figure) and proceeds by units of three bases (codons). The normal reading frame is referred to as the 0 frame, that missing a base the -1 frame, and that with an extra base the $+1$ frame.

result of errors during genetic recombination. In addition, many large insertion mutations are due to the insertion of specific DNA sequences called *transposable elements* (Section 9.11).

We will discuss the effects of mutations on the evolution of bacterial genomes in Chapter 13.

Check Your Understanding

- Do missense mutations occur in genes encoding tRNA? Why or why not?
- Why do frameshift mutations generally have more serious consequences than missense mutations?

9.3 Reversions and Mutation Rates

The rates at which the different kinds of mutations occur vary widely. Some mutations occur so rarely that they are almost impossible to detect, whereas others occur so frequently that they present difficulties for an experimenter trying to maintain a genetically stable stock culture. Sometimes a second mutation can reverse the effect of an initial mutation. Furthermore, all organisms possess a variety of systems for DNA repair. Consequently, the observed mutation rate depends not only on the frequency of DNA changes but also on the efficiency of DNA repair.

Reversions (Back Mutations) and Suppressors

Point mutations are typically reversible, a process known as **reversion**. A *revertant* is therefore a strain in which the original phenotype that was changed by mutation is restored by a second mutation. Revertants can be of two types, same site or second site. In *same-site* revertants, the mutation that restores activity is at the same site as the original mutation. If the back mutation is not only at the same site but also restores the original sequence, it is called a *true* revertant.

In *second-site* revertants, the mutation is at a different site in the DNA. Second-site mutations can restore a wild-type phenotype if

they function as *suppressor mutations*—mutations that compensate for the effect of the original mutation. Several classes of suppressor mutations are known. These include (1) a mutation somewhere else in the same gene that restores enzyme function, such as a second frameshift mutation near the first that restores the original reading frame (Figure 9.6); (2) a mutation in another gene that restores the function of the original mutated gene; and (3) a mutation in another gene that results in the production of an enzyme that can replace the nonfunctional one.

Suppressors can be best illustrated by mutations in tRNAs. Nonsense mutations can be suppressed by changing the anticodon sequence of a tRNA molecule so that it now recognizes a stop codon (Figure 9.7). Such an altered tRNA is called a *suppressor tRNA* and will insert the amino acid it carries at the stop codon that it now reads. Suppressor tRNA mutations exist in all three domains of life, and their activity has been observed in both *Bacteria* and *Archaea* by introducing reporter genes (◀ Section 8.1) containing nonsense mutations. During these experiments, complete translation and activity of the corresponding reporter protein was observed despite the presence of a stop codon within the coding region of the reporter.

Suppressor tRNA mutations would be lethal unless a cell has more than one tRNA gene for a particular codon. One tRNA gene may then be mutated to produce a suppressor, while the other gene's product performs the original function. Most cells have multiple genes for

Figure 9.7 Suppression of nonsense mutations. Introduction of a nonsense mutation in a gene encoding a protein results in the incorporation of a stop codon (indicated by the *) in the corresponding mRNA. This single mutation leads to the production of a truncated polypeptide. The mutation is suppressed if a second mutation occurs in the anticodon of a tRNA, a tRNA charged with glutamine in this example, which allows the mutated tRNA or suppressor tRNA to bind to the nonsense codon.

tRNAs, and so suppressor mutations are reasonably common, at least in microorganisms. Sometimes the amino acid inserted by the suppressor tRNA is identical to the original amino acid and the protein is fully active. In other cases, however, a different amino acid is inserted and a protein that is only partially active may be produced.

Mutation Rates

For most microorganisms, errors in DNA replication occur at a frequency of 10^{-6} to 10^{-7} per thousand bases during a single round of replication. A typical gene has about 1000 base pairs. Therefore, the frequency of a mutation *in a given gene* is also in the range of 10^{-6} to 10^{-7} per round of replication. For instance, in a bacterial culture having 10^8 cells/ml, there are likely to be a number of different mutants for any given gene in each milliliter of culture. Eukaryotes with very large genomes tend to have replication error rates about 10-fold lower than typical bacteria, whereas DNA viruses, especially those with very small genomes, may have error rates 100-fold to 1000-fold higher than those of cellular organisms. RNA viruses have even higher error rates due to less effective polymerase proofreading (◀ Section 6.4) and the lack of RNA repair mechanisms.

Single base errors during DNA replication are more likely to lead to missense mutations than to nonsense mutations because most single base substitutions yield codons that encode other amino acids (◀ Table 6.4). The next most frequent type of codon change caused by a single base change leads to a silent mutation. This is because for the most part alternate codons for a given amino acid differ from each other by a single base change in the “silent” third position. A given codon can be changed to any of 27 other codons by a single base substitution, and on average, about two of these will be silent mutations, one a nonsense mutation, and the rest missense mutations.

Unless a mutation can be selected for, its experimental detection is difficult, and much of the skill of the microbial geneticist requires increasing the efficiency of mutation detection. This can

be done most effectively by increasing the pool of mutations. As we see in the next section, it is possible to greatly increase the mutation rate by treatment with mutagenic agents. In addition, the mutation rate may change under certain circumstances, such as when cells are placed under high-stress conditions.

Check Your Understanding

- Why are suppressor tRNA mutations not lethal?
- Which class of mutation, missense or nonsense, is more common, and why?

9.4 Mutagenesis

The spontaneous rate of mutation is very low, but a variety of chemical, physical, and biological agents can increase the mutation rate and are therefore said to induce mutations. These agents are called **mutagens**. Because *Bacteria* and *Archaea* are often exposed to mutagens, not only intentionally in the laboratory but also accidentally in their environment, we discuss some of the major categories of mutagens and their activities here.

Chemical Mutagens and Radiation

An overview of some of the major chemical mutagens and their modes of action is given in Table 9.2. Several classes of chemical mutagens exist. The *nucleotide base analogs* are molecules that resemble the purine and pyrimidine bases of DNA in structure but display faulty base-pairing properties (Figure 9.8). If a base analog is incorporated into DNA in place of the natural base, the DNA may replicate normally most of the time. However, DNA replication errors occur at higher frequencies at these sites due to incorrect base pairing. The result is the incorporation of a mismatched base into the new strand of DNA and thus introduction of a mutation. During subsequent segregation of this strand in cell division, the mutation is revealed.

TABLE 9.2 Chemical and physical mutagens and their modes of action

Agent	Action	Result
Base analogs		
5-Bromouracil	Incorporated like T; occasional faulty pairing with G	AT → GC and occasionally GC → AT
2-Aminopurine	Incorporated like A; faulty pairing with C	AT → GC and occasionally GC → AT
Chemicals that react with DNA		
Nitrous acid (HNO ₂)	Deaminates A and C	AT → GC and GC → AT
Hydroxylamine (NH ₂ OH)	Reacts with C	GC → AT
Alkylating agents		
Monofunctional (for example, ethyl methanesulfonate)	Puts methyl on G; faulty pairing with T	GC → AT
Bifunctional (for example, mitomycin, nitrogen mustards, nitrosoguanidine)	Cross-links DNA strands; faulty region excised by DNase	Both point mutations and deletions
Intercalating agents		
Acridines, ethidium bromide	Inserts between two base pairs	Microinsertions and microdeletions
Radiation		
Ultraviolet (UV)	Pyrimidine dimer formation	Repair may lead to error or deletion
Ionizing radiation (for example, X-rays)	Free-radical attack on DNA, breaking chain	Repair may lead to error or deletion

Figure 9.8 Nucleotide base analogs. Structure of two common nucleotide base analogs used to induce mutations compared with the normal nucleic acid bases for which they substitute. (a) 5-Bromouracil can base-pair with guanine, causing AT to GC substitutions. (b) 2-Aminopurine can base-pair with cytosine, causing AT to GC substitutions.

Other chemical mutagens induce *chemical modifications* in one base or another, resulting in faulty base pairing or related changes (Table 9.2). For example, alkylating agents (chemicals that react with amino, carboxyl, and hydroxyl groups by substituting them with alkyl groups) such as nitrosoguanidine are powerful mutagens and generally induce mutations at higher frequency than base analogs. Unlike base analogs, which have an effect only when incorporated during DNA replication, alkylating agents can introduce changes even in nonreplicating DNA. Both base analogs and alkylating agents tend to induce base-pair substitutions (Section 9.2).

Another group of chemical mutagens, the acridines, are planar molecules that function as *intercalating agents*. These mutagens become inserted between two DNA base pairs and push them apart. Then, during replication, this abnormal conformation can trigger single base insertions or deletions. Thus, acridines typically induce frameshift rather than point mutations (Section 9.2). Ethidium bromide, which is commonly used to detect DNA in gel electrophoresis, is also an intercalating agent and therefore a mutagen.

Nonionizing and *ionizing* radiation are two forms of electromagnetic radiation that are highly mutagenic (Figure 9.9). Ultraviolet (UV) radiation is widely used to generate mutations because the purine and pyrimidine bases of nucleic acids absorb UV radiation strongly (the absorption maximum for DNA and RNA is at 260 nm). The primary mutagenic effect is the production of *pyrimidine dimers*, in which two adjacent pyrimidine bases (cytosine or thymine) on the same strand of DNA become covalently bonded to one another. This either greatly impedes DNA polymerase activity or greatly increases the probability of DNA polymerase misreading the sequence at this point. Thus the killing of cells by UV radiation

Figure 9.9 Wavelengths of radiation. Ultraviolet radiation consists of wavelengths just shorter than visible light. For any electromagnetic radiation, the shorter the wavelength, the higher the energy. DNA absorbs strongly at 260 nm.

is due primarily to its effect on DNA. Conversely, ionizing radiation is more powerful than UV radiation and includes short-wavelength radiation such as X-rays, cosmic rays, and gamma rays (Figure 9.9). These rays cause water and other substances to ionize, resulting in the formation of free radicals such as the hydroxyl radical ($\text{OH}\cdot$, Section 4.16) that can damage macromolecules in the cell, including DNA. This causes double-stranded and single-stranded breaks that may lead to rearrangements or large deletions.

DNA Repair and the SOS System

By definition, a mutation is a *heritable* change in the genetic material. Therefore, if damaged DNA can be corrected before the cell divides, no mutation will occur. While cells have a variety of different DNA repair processes to correct mistakes (Section 6.4) or repair damage, some are error-prone and the repair process itself introduces the mutation. Some types of DNA damage, especially large-scale damage from highly mutagenic chemicals or large doses of radiation, may cause lesions that interfere with replication. If such lesions are not removed before replication occurs, DNA replication will stall and lethal breaks in the chromosome will result.

In *Bacteria*, stalled replication or major DNA damage activates the **SOS repair system**. The SOS system initiates a number of DNA repair processes, some of which are error-free. However, the SOS system also allows DNA repair to occur without a template, that is, with random incorporation of nucleotide precursors (deoxyribonucleotide triphosphates [dNTPs]). As might be expected, this results in many errors and hence many mutations. However, mutations induced by the SOS repair system are better than the alternative (death of the cell), as mutations can often be corrected while chromosome breaks usually cannot.

In *Escherichia coli* the SOS repair system controls the transcription of approximately 40 genes located throughout the chromosome that

Figure 9.10 SOS response to DNA damage. DNA damage activates RecA protein, which in turn activates the protease activity of LexA, resulting in self-cleavage. LexA normally represses the activities of RecA, the genes *uvrA* and *umuCD* that encode DNA repair functions (the UmuCD proteins are part of DNA polymerase V), and *dinB*, which encodes DNA polymerase IV. However, repression is not complete. Some

RecA protein is produced even in the presence of LexA protein. When LexA is inactivated, DNA repair genes are highly transcribed. Inset photos: Both photos show DNA polymerase IV localization to the nucleoid during the SOS response in *Escherichia coli*. Cells containing a fluorescently tagged DNA polymerase IV (DinB) were treated with an antibiotic to induce DNA damage. Left: phase-contrast micrograph. Right: fluorescence

micrograph showing cells stained with DAPI (blue) and DNA polymerase IV (yellow, in the nucleoid region). Expression of *dinB* requires not only the loss of LexA repression but also the protein RpoS, an RNA polymerase sigma factor whose synthesis is triggered by various stress responses.

participate in DNA damage tolerance and DNA repair. Not only does the SOS system form a regulon, but the *general stress response* or *RpoS regulon* also plays a role in the repair system (◀ Sections 7.3 and 7.9). In DNA damage tolerance, DNA lesions remain in the DNA, but are bypassed by specialized DNA polymerases that can move past DNA damage—a process called *translesion synthesis*. Even if no template is available to allow insertion of the correct bases, it is less dangerous to cell survival in the long run to fill the gap than to let it remain. Consequently, translesion synthesis generates many errors. In *E. coli*, in which the process of mutagenesis has been studied in great detail, the two error-prone repair polymerases are DNA polymerase V, an enzyme encoded by the *umuCD* genes, and DNA polymerase IV, encoded by *dinB* (Figure 9.10). Both are induced as part of the SOS repair system.

The master regulators of the SOS system are the proteins LexA and RecA. LexA is a repressor that normally prevents expression of the SOS system. The RecA protein, which normally functions in genetic recombination (Section 9.5), is activated by the presence of DNA damage, in particular by the single-stranded DNA that results when replication stalls. The activated form of RecA then stimulates LexA to inactivate itself by self-cleavage. This leads to derepression of the SOS system and the coordinate expression of proteins that participate in DNA repair. Because some of the DNA repair mechanisms of the SOS system—such as DNA polymerases IV and V—are inherently error-prone, many mutations arise. However, once the original DNA damage has been repaired, the SOS regulon is repressed and further mutagenesis ceases.

Besides controlling some DNA repair systems and error-prone polymerases, the SOS system also regulates processes that contribute

to *horizontal gene transfer*, which we discuss next. Thus, uptake and recombination of foreign DNA can also be used by *Bacteria* and *Archaea* to fix chromosomal breaks. As we shall see in Part II, not only does this form of DNA repair help with cell survival, but it also can increase cell diversity.

Check Your Understanding

- How do mutagens cause mutations?
- What is meant by “error-prone” DNA repair?

II • Gene Transfer in *Bacteria*

Lateral gene flow within and between species of *Bacteria* is highly dynamic and facilitated by at least three different mechanisms. Such genetic exchange is distinct from traditional mother-to-daughter inheritance and allows cells to rapidly acquire new characteristics and increase their competitive fitness.

Comparative genomic analyses of closely related microbes that exhibit different phenotypes have revealed distinct genome differences. Often these idiosyncratic differences result from *horizontal gene transfer*, the movement of genes between cells that are not direct descendants of one another (▶ Section 13.9). Horizontal gene transfer allows cells to quickly acquire new characteristics and fuels metabolic diversity.

Three mechanisms of genetic exchange are known in bacteria: (1) *transformation*, in which free DNA released from one cell is taken up by another (Section 9.6); (2) *transduction*, in which DNA transfer is mediated by a virus (Section 9.7); and (3) *conjugation*, in which DNA transfer requires cell-to-cell contact and a conjugative plasmid in the donor cell (Sections 9.8 and 9.9). While these processes were presented in Figure 9.1, they are compared and contrasted in **Figure 9.11**. It should be noted that DNA transfer typically occurs in only one direction, from donor to recipient.

Before discussing the mechanisms of transfer, we consider the fate of transferred DNA. Regardless of how it was transferred, DNA that enters the cell by horizontal gene transfer faces three possible fates: (1) It may be degraded by the recipient cell's restriction enzymes or other DNA destruction systems (Section 9.12); (2) it may replicate

by itself (but only if it possesses its own origin of replication, such as a plasmid or phage genome); or (3) it may recombine with the recipient cell's chromosome.

9.5 Genetic Recombination

Recombination is the physical exchange of DNA between *genetic elements* (structures that carry genetic information). Here we focus on *homologous recombination*, a process that results in genetic exchange between homologous DNA sequences from two different sources. Homologous DNA sequences are those that have nearly the same sequence; therefore, bases can pair over an extended length of the two DNA molecules to facilitate exchange. This type of recombination is often essential to a cell's ability to retain DNA following genetic exchange and is behind the well-known phenomenon of “crossing over” in the genetics of eukaryotes.

Molecular Events in Homologous Recombination

The RecA protein, previously mentioned in regard to the SOS repair system (Section 9.4 and Figure 9.10), is the key to homologous recombination. RecA is essential in nearly every homologous recombination pathway. RecA-like proteins have been identified in all *Bacteria* examined, as well as in the *Archaea* and most *Eukarya*.

A molecular mechanism for homologous recombination between two DNA molecules is shown in **Figure 9.12**. An enzyme that cuts DNA in the middle of a strand, called an *endonuclease*, begins the process by nicking one strand of the donor DNA molecule. This nicked strand is separated from the other strand by proteins with helicase activity; the resulting single-stranded segment binds single-strand binding protein (◀ Section 6.3) and then RecA. This results in a complex that promotes base pairing with the complementary sequence in the recipient DNA molecule. Base pairing, in turn, displaces the other strand of the recipient DNA molecule (Figure 9.12) and is appropriately called *strand invasion*.

The base pairing of one strand from each of the two DNA molecules over long stretches generates recombination intermediates containing long **heteroduplex** regions, where each strand has originated from a different chromosome. After DNA strands at the branch or crossover regions are joined, the linked molecules are then resolved (separated) by enzymes that cut and rejoin the previously unbroken strands of both original DNA molecules. Depending on the orientation of the junction during resolution, two types of products—referred to as “patches” or “splices”—are formed that differ in the conformation of the heteroduplex regions remaining after resolution (Figure 9.12).

Effect of Homologous Recombination on Genotype

For homologous recombination to generate new genotypes, the two homologous sequences must be related but genetically distinct. This is obviously the case in a diploid eukaryotic cell, which has two sets of chromosomes, one from each parent. However, in bacteria, genetically distinct but homologous DNA molecules are brought together in different ways. Genetic recombination in bacteria occurs after fragments of homologous DNA from a donor chromosome are transferred to a recipient cell by transformation, transduction, or conjugation. It is only after the transfer event, when the DNA fragment from the donor is in the recipient cell, that homologous recombination occurs.

Figure 9.11 Processes by which DNA is transferred from donor to recipient bacterial cell. Just the initial steps in transfer are shown. Note that conjugation requires cell–cell contact, whereas transduction and transformation do not.

Figure 9.12 Homologous recombination. Homologous DNA molecules pair and exchange DNA segments. The mechanism requires breakage and reunion of paired segments, as indicated by red arrows. Two of the participating proteins, single-strand binding (SSB) protein and the RecA protein, are shown (other participating proteins are not shown). Resolution occurs by cutting and rejoining the cross-linked DNA molecules. Note that there are two possible outcomes, patches or splices, depending on where strands are cut during the resolution process.

For physical exchange of DNA segments to be detected, the cells resulting from recombination must be phenotypically different from both parents (**Figure 9.13**). Genetic crosses in bacteria usually depend on using recipient strains that lack some selectable character that the recombinants will gain. For instance, the recipient may be

Figure 9.13 Using a selective medium to detect rare genetic recombinants. On the selective medium, only the rare recombinants form colonies even though a very large population of bacteria is plated. Procedures such as this, which offer high resolution for genetic analyses, can ordinarily be used only with microorganisms. The type of genetic exchange being illustrated is transformation, but a similar outcome could result from any of the other forms of horizontal gene transfer (**Figure 9.1**).

unable to grow on a particular medium or may exhibit a specific phenotype due to a point mutation, while the genetic recombinants can grow on the particular medium or exhibit a phenotype different from the recipient (**Figures 9.2 and 9.13**). Various kinds of selectable markers, such as drug resistance and nutritional requirements, were discussed in Section 9.1. The exceedingly great sensitivity of the selection process allows even a few recombinant cells to be detected in a large population of nonrecombinant cells, and thus selection is an important tool for the microbial geneticist.

Complementation

In all three methods of bacterial gene transfer, only a portion of the donor chromosome enters the recipient cell and thus transfer is just the first step; unless recombination takes place with the recipient chromosome, the donor DNA will be lost because it cannot replicate independently in the recipient. Nonetheless, it is possible to stably maintain a state of partial diploidy for use in bacterial genetic analysis. A bacterial strain that carries *two copies* of any particular chromosomal segment is known as a partial diploid, or *merodiploid*. In general, one copy is present on the chromosome itself and the second copy on another genetic element, such as a plasmid or a bacteriophage.

Consequently, if the chromosomal copy of a gene is defective due to a mutation, it is possible to supply a functional (wild-type) copy of the gene on a plasmid or bacteriophage. For example, if one of the genes for biosynthesis of the amino acid tryptophan has a mutation resulting in a nonfunctional enzyme, this will yield a Trp⁻ phenotype (the mutant strain will be a tryptophan auxotroph and must be supplied with tryptophan for growth). However, if a copy of the wild-type gene is introduced into the same cell on a plasmid or viral genome, this gene will encode the necessary protein and, assuming the gene is transcribed and translated, will restore the wild-type phenotype. This process is called *complementation* because the wild-type gene is said to *complement* the mutation, in this case converting the Trp⁻ cell into Trp⁺ (**Figure 9.13**).

Check Your Understanding

- Which protein, found in virtually all cells, facilitates the pairing required for homologous recombination?
- Explain the fate of transferred chromosomal DNA if recombination does not occur in the recipient cell.
- What is a merodiploid, and what is genetic complementation?

9.6 Transformation

Transformation is a genetic transfer process by which *free DNA* is incorporated into a recipient cell and brings about genetic change. When would a cell encounter free DNA? Because the DNA in bacterial and archaeal cells is present as a large single molecule, chromosomal DNA pours out during cell lysis. Cells that are naturally transformable, which include certain species of both gram-negative and gram-positive *Bacteria* and also some species of *Archaea* (Section 9.10), can take up pieces of this free DNA from their lysed neighbors (Figures 9.1 and 9.11).

Because of their extreme length, bacterial chromosomes break easily. For example, the *Bacillus subtilis* chromosome would be 1700 μm long if linearized. However, even gentle DNA extraction methods result in the *B. subtilis* 4.2-megabase-pair chromosome being broken into fragments of about 10 kilobase pairs each. Because an average gene contains about 1000 nucleotides, each of the fragments of *B. subtilis* DNA contains about ten genes. This is a typical transformable size. A single cell typically incorporates only one or at most a few DNA fragments, so only a small proportion of the genes of one cell can be transferred to another in a single transformation event.

Competence in Transformation

How does a cell take up DNA? Recall from our Chapter 2 discussion that cell membranes are selective barriers. DNA does not freely cross this barrier; thus a cell that is able to take up DNA and be transformed is said to be *competent*. **Figure 9.14** illustrates *Vibrio cholerae*, the causative agent of cholera and a model gram-negative bacterium

Figure 9.14 *Vibrio cholerae* killing neighboring prey cells and scavenging DNA. Time-course images of *V. cholerae* type VI secretion system proteins labeled with a green fluorescent protein (GFP) and corresponding DNA uptake proteins labeled with a red fluorescent protein. *V. cholerae* cells expressing both protein types appear red with green “crossbows” inside, while competing cells lacking a type VI secretion system appear as solid green cells. At time 0, white arrows indicate prey cells that have been killed. These cells circularize upon death. After 30 minutes, DNA uptake proteins localize for effective uptake of DNA from killed cells (circled). Images modified from Borgeaud, S., Metzger, L.C., Scrinari, T., and Blokesch, M. 2015. *Science* 347: 63–67.

for natural competence, taking up DNA. In its natural marine environment, *V. cholerae* aggressively competes for nutrients by using its type VI secretion system to inject toxin molecules into neighboring cells (◀ Section 6.13). These toxin molecules ultimately kill competitor cells. Not only do the *V. cholerae* cells obtain nutrients from lysed neighboring cells, but they are also able to scavenge the DNA released from their victims (Figure 9.14).

The capacity to take up free DNA is genetically determined. In *Bacteria* such as *Vibrio*, *Neisseria*, *Acinetobacter*, *Thermus*, *Streptococcus*, and *Bacillus*, competence is directly linked to pili (**Figure 9.15**). Pili

Figure 9.15 *Vibrio* pilus and DNA uptake. (a) Transmission electron micrograph showing *Vibrio cholerae* type IV pilus. (b) The pilus binds extracellular DNA, and (c) pilus retraction brings extracellular DNA through the outer membrane to the competence (Com) system associated with the cytoplasmic membrane. See the photomicrograph of a *V. cholerae* cell using its pilus to retrieve DNA on page 297.

are versatile multiprotein structures that not only play roles in twitching, gliding motility, biofilm formation, and pathogenesis (◀ Sections 2.6 and 2.10), but are also key to binding and taking up DNA in naturally competent cells. In gram-negative *Bacteria*, pili cross the hydrophobic outer membrane through a specific channel, and protein subunits within the pilus recognize and bind to extracellular DNA (Figure 9.15b). After binding to DNA, *V. cholerae* pili pull the DNA through the outer membrane into the periplasm through a process called *pilus retraction* (see MicrobiologyNow in the chapter opener). This retraction of the pilus is the result of depolymerization of individual pilin proteins that make up the pilus structure (Figure 9.15c). In gram-positive cells, pili or homologs of type II secretion systems (◀ Section 6.13) are used to bind DNA and bring it through the thick cell wall layer. Once in the periplasm of gram-negative cells or through the cell wall in gram-positive cells, the DNA binds to proteins within the *competence system* associated with the cytoplasmic membrane. These competence-specific proteins include a membrane-associated DNA-binding protein and various nucleases (Figure 9.16).

As noted earlier, the sizes of the transforming fragments are much smaller than that of the whole genome, and the fragments are further degraded during the uptake process by competence proteins (Figure 9.16). As these fragments are taken up into the cytoplasm, they are often converted into single-stranded pieces of DNA, with the complementary strand being degraded. After entry into the cytoplasm, a competence-specific protein binds the single-stranded donor DNA. This protects the DNA from nuclease attack until it reaches the recipient's chromosome, where the RecA protein takes over. If the transforming DNA shares sequence homology with that of the chromosome, then it is integrated into the genome of the recipient by recombination (Figures 9.12 and 9.16).

The preceding applies only to small pieces of *linear* DNA. Many naturally transformable *Bacteria* are transformed only poorly by plasmid DNA because the plasmid must remain double-stranded and circular in order to replicate. The success rate of natural plasmid DNA transformation can be enhanced through delivery

from a donor to a recipient cell through extracellular vesicles (Figure 9.1), which we will consider in more detail in *Archaea* in Section 9.10.

Regulation of Competence

Competence in most naturally transformable bacteria is regulated. One pathway of natural competence in *Bacillus subtilis*—an easily transformed species—is regulated by quorum sensing, a regulatory system that responds to cell density (◀ Section 7.7). Cells produce and excrete a small peptide during growth, and the accumulation of this peptide to high concentrations induces the cells to become competent. But not all cells in a population become competent. In *Bacillus*, roughly 20% of the cells become competent and stay that way for several hours. By contrast, in *Streptococcus*, 100% of the cells can become competent, but only for a brief period during the growth cycle.

Multiple layers of regulation control natural competence in other bacteria. *Vibrio cholerae* is naturally found in marine and freshwater environments associated with crustacean exoskeletons, which are composed of chitin. Competence in *V. cholerae* is controlled not only by quorum sensing but also by chitin sensing and catabolite repression (◀ Section 7.8). *V. cholerae* can catabolize chitin (a polymer of *N*-acetylglucosamine and an abundant nutrient in the marine environment), and as cells aggregate on a chitin surface, they are in close proximity to one another and more likely to successfully exchange DNA (Figure 9.17).

High-efficiency, natural transformation is rare among *Bacteria*. For example, *Acinetobacter*, *Bacillus*, *Streptococcus*, *Haemophilus*, *Neisseria*, and *Thermus* are naturally competent and easy to transform. This natural competence provides a nutritional advantage, as free DNA is rich in carbon, nitrogen, and phosphorus. By contrast, many *Bacteria* are poorly transformed, if at all, under natural conditions. For example, *Escherichia coli* and many other gram-negative bacteria fall into this category. However, if cells of *E. coli* are treated with high concentrations of Ca^{2+} and then chilled, they become adequately competent. Cells treated in this manner take up double-stranded

Figure 9.16 General mechanism of transformation. To begin, double-stranded DNA is bound by a membrane-bound DNA-binding protein. Passage of one of the two strands of DNA into the cell is followed by nuclease activity that degrades the complementary strand. Once the single strand of DNA in the cell is bound by specific proteins, recombination with homologous regions of the bacterial chromosome is mediated by the RecA protein with the final product being a transformed cell.

Figure 9.17 Regulation of natural competence in *Vibrio cholerae*. *V. cholerae* cells with fluorescent reporter genes linked to the promoters of competence genes were grown in the presence of chitin beads. White dashed line indicates edge of bead surface. (a) Cells with the *pilA* (pilus protein) promoter linked to a green fluorescent protein (GFP). (b) Cells with the *comEA* (DNA uptake proteins) promoter linked to a red fluorescent protein. (c) Merged image of parts a and b illustrating expression of competence genes in cells associated with the chitin bead. Cells of *V. cholerae* are about 0.5 μm wide and 1.5 μm long. DNA, and therefore transformation of *E. coli* by plasmid DNA can be relatively efficient. This is important because getting DNA into *E. coli*—the workhorse of genetic engineering—is critical for biotechnology, as we will see in Chapter 12.

Electroporation is a physical technique that is used to get DNA into organisms that are difficult or impossible to transform, especially cells that contain thick cell walls. In electroporation, cells are mixed with DNA and then exposed to brief, high-voltage electrical pulses. This makes the cell envelope permeable and allows entry of the DNA. Electroporation works for getting free DNA into most types of cells, including *E. coli*, most other *Bacteria*, some species of *Archaea*, and even yeast and certain plant cells.

- In genetic transformation, what is meant by the word competence?
- During natural competence, what type of cellular structure is used to bind DNA and take it to the cytoplasmic membrane?

9.7 Transduction

In **transduction**, a bacterial virus (bacteriophage, Chapter 5) transfers DNA from one cell to another. Viruses can transfer host genes in two ways. In the first, called *generalized transduction*, DNA derived from virtually any portion of the host genome is packaged inside the mature virion in place of the virus genome. In the second, called *specialized transduction*, DNA from a specific region of the host chromosome is integrated directly into the virus genome—usually replacing some of the virus genes. This occurs only with certain temperate viruses such as phage lambda (◀ Section 5.6).

In generalized transduction, the bacterial donor genes cannot replicate independently and are not part of a viral genome. Thus, unless the donor genes recombine with the recipient bacterial chromosome, they will be lost. In specialized transduction, homologous

recombination may also occur. However, since the donor bacterial DNA is actually a part of a temperate phage genome, it may be integrated into the host chromosome during lysogeny (◀ Section 5.6). This can lead to an event called phage conversion (see later).

Transduction occurs in a variety of *Bacteria*, including the genera *Desulfovibrio*, *Escherichia*, *Pseudomonas*, *Rhodococcus*, *Rhodobacter*, *Salmonella*, *Staphylococcus*, and *Xanthobacter*, as well as *Methanotermobacter thermautotrophicus*, a species of *Archaea*. Not all phages can transduce and not all bacteria are transducible. However, considering the enormous genetic diversity of viruses (Chapter 11) and the fact that bacteriophages are estimated to outnumber prokaryotic cells in nature by 10-fold, transduction likely plays an important role in gene transfer in the environment for many species of *Bacteria* and *Archaea*. Some examples of genes transferred by transducing bacteriophages include multiple-antibiotic-resistance genes among strains of *Salmonella enterica* (*typhimurium*), Shiga-like toxin genes in *Escherichia coli*, virulence factors in *Vibrio cholerae*, and genes encoding photosynthetic proteins in cyanobacteria (▶ Section 20.13).

Generalized Transduction

In generalized transduction, virtually any gene on the donor chromosome can be transferred to the recipient, forming a *transductant*. Generalized transduction was first discovered and extensively studied in the bacterium *S. enterica* with phage P22 and has also been studied with phage P1 in *E. coli*. The mechanism of transduction is shown in Figure 9.18. When a bacterial cell is infected with a transducing phage, the lytic cycle may occur. However, during lytic infection, the enzymes responsible for packaging viral DNA into the bacteriophage sometimes package host DNA accidentally. The result is called a *transducing particle*. These cannot lead to a viral lytic infection because they contain no viral DNA, and are therefore said to be *defective*.

Upon lysis of the cell, transducing particles are released along with normal virions that contain the virus genome. When this

Lytic cycle

Figure 9.18 Generalized transduction. Note that “normal” virions contain phage genes, whereas a transducing particle contains host genes.

lysate is used to infect a population of recipient cells, most of the cells are infected with a normal (lytic) virus. However, a small proportion of the population receives transducing particles that inject the DNA they packaged from the previous host bacterium. Although this DNA cannot replicate, it can recombine with the DNA (Section 9.5) of the new host (**Figure 9.19**). Because only a small proportion of the particles in the lysate are defective, and each of these contains only a small fragment of donor DNA, the probability of a given transducing particle containing a particular gene is quite low. Typically, only about 1 cell in 10^6 to 10^8 cells is transduced for any given gene.

Lysogeny and Specialized Transduction

Generalized transduction allows the transfer of any gene from one bacterium to another, but at a low frequency. In contrast, specialized transduction allows extremely efficient transfer but is selective and transfers only a small region of the bacterial chromosome. In the first case of specialized transduction to be discovered, genes for galactose catabolism were transduced by the temperate phage lambda of *E. coli*.

When lambda lysogenizes a host cell, the phage genome is integrated into the *E. coli* chromosome at a specific site (◀ Section 5.6

and ▶ Section 11.4). This site is next to the cluster of genes that encode the enzymes for galactose utilization. After insertion, viral DNA replication is under control of the bacterial host chromosome. Upon induction, the viral DNA separates from the host DNA by a process that is the reverse of integration (**Figure 9.20**). Usually the lambda DNA is excised precisely, but occasionally the phage genome is excised incorrectly. Some of the adjacent bacterial genes to one side of the prophage (for example, the galactose operon) are excised along with phage DNA. At the same time, some phage genes are left behind (**Figure 9.20b**). This transducing particle can subsequently transfer genes for galactose utilization to a recipient cell. This transfer can only be detected if a galactose-negative (Gal^-) strain is infected with such a transducing particle and Gal^+ transductants are selected.

For a lambda virion to be infectious, there is a limit to the amount of phage DNA that can be replaced with host DNA. Sufficient phage DNA must be retained to encode the phage protein coat and other phage proteins needed for lysis and lysogeny. However, if a helper phage is used together with a defective phage in a *mixed infection*, then far fewer phage-specific genes are needed in the defective phage. Only the *att* (attachment) region, the *cos* site (cohesive ends, for packaging), and the replication origin of the lambda genome (▶ **Figure 11.11**) are necessary.

Phage Conversion

Alteration of the phenotype of a host cell by lysogenization is called *phage conversion*. When a normal (that is, nondefective) temperate phage lysogenizes a cell and becomes a prophage, the cell becomes immune to further infection by the same type of phage. Such immunity may itself be regarded as a change in phenotype. However, other phenotypic changes unrelated to phage immunity are often observed in phage conversion of lysogenized cells due to foreign genes present in the phage genome.

Overall, the genes responsible for the phage conversion are an integral part of the phage genome and hence are automatically

transferred to the cell upon phage infection and establishment of the lysogenic state. This lysogenic state likely carries strong selective value for the host cell because it confers resistance to infection by viruses of the same type. It has also been found that many bacteria isolated from nature are natural lysogens and that their corresponding prophage encode an abundance of transposons (Section 9.11

and ▶ Section 13.9). Thus it is likely that phage conversion contributes to the formation of new genes that are essential for survival of many host cells in nature.

Cases of phage conversion that promote bacterial virulence have been especially well studied. *Vibrio cholerae*, which causes the disease cholera (▶ Section 33.3), is a fascinating example of how phage conversion can result in a nonpathogenic environmental strain evolving into a pathogen. CTX ϕ is a lysogenic bacteriophage found integrated into the chromosome of pathogenic *V. cholerae* strains. Besides the normal genes necessary to maintain the lysogenic state, the CTX ϕ prophage also encodes the cholera toxin that triggers the diarrheal disease. During infection, CTX ϕ virions specifically bind to the toxin co-regulated pilus (TCP) used by *V. cholerae* to attach to host intestinal cells (▶ Section 33.3). Interestingly, this TCP appears to be encoded by a separate prophage. Strains of *Vibrio* that are not lysogenized by CTX ϕ or TCP are nonpathogenic, thus highlighting the power of phage conversion in enhancing genetic fitness and pathogen evolution. In later chapters we will see many other human infectious diseases in which phage conversion plays a critical role, including in such distinct diseases as whooping cough and botulism.

Gene Transfer Agents

DNA can also be transferred between prokaryotic cells by defective bacteriophages. These so-called *gene transfer agents* (GTAs) are the result of prokaryotic cells hijacking defective viruses and using them specifically for DNA exchange (Figure 9.21). GTAs resemble tiny tailed bacteriophages and contain random small pieces of *host* DNA. They are not considered true viruses because they do not contain genes encoding their own production and do not produce characteristic viral plaques. Instead, the genes encoding GTAs lie within the genome of the cell that produces them, while other regions of the genome are packaged within the agents.

Figure 9.21 Gene transfer agents. Inset: Transmission electron micrograph of a gene transfer agent (GTA) isolated from *Rhodobacter capsulatus*. Visualization of a subset of *R. capsulatus* cells producing and releasing GTAs during stationary phase using a red fluorescent reporter gene linked to the promoter of an *R. capsulatus* gene essential for GTA production. Note that only a subset of the total population produces GTA.

GTAs have been isolated from a wide range of *Bacteria* including the sulfate-reducing bacterium *Desulfovibrio desulfuricans*, a variety of phototrophic purple bacteria and other *Alphaproteobacteria*, and also from certain methanogenic *Archaea*. GTAs seem to be particularly widely produced by marine *Bacteria*, especially purple bacteria such as *Roseovarius*. GTA synthesis is regulated, and in the purple bacterium *Rhodobacter capsulatus*, GTA synthesis is triggered by the cell's sensing of the stationary growth phase and nutrient fluctuations (Figure 9.21). These conditions lead to only a small subpopulation of *R. capsulatus* cells lysing and releasing the GTAs. However, the same conditions that trigger GTA synthesis in some cells also lead to increased expression of the genes encoding products necessary for the uptake of GTAs. In *R. capsulatus*, stationary phase and nutrient fluctuations lead to the increased expression of genes encoding the capsular polysaccharide (◀ Figure 2.16) receptor that GTAs specifically bind to and natural competence proteins needed for DNA uptake. This suggests that GTAs may have evolved as a mechanism for a subpopulation of cells to sacrifice themselves in order to disperse genes into the environment in a protected form to benefit the rest of their population.

While bacteriophages are considered the most abundant microbes on Earth, the percentage of these that are actually GTAs instead of viruses is unknown, but could be significant. The fact that GTAs are produced by so many different species points to GTAs as major vehicles for gene flow between prokaryotic cells in nature. This could be especially true of open-ocean microbial communities, where constant low nutrient levels might trigger GTA production as a means for cells to scavenge each other's genes in an effort to improve fitness and survival of the overall population.

9.8 Conjugation

Conjugation is a form of horizontal gene transfer that requires cell-to-cell contact (mating) and occurs in many species of gram-negative and gram-positive bacteria. Conjugation is a plasmid-encoded mechanism that can mediate DNA transfer between closely related cells or between more distantly related cells (for example, between cells of different genera). Conjugative plasmids use conjugation to transfer copies of the genes that encode themselves and other genes they may contain, such as those that encode antibiotic resistance, to new host cells.

The process of conjugation requires a *donor* cell, which contains the conjugative plasmid, and a *recipient* cell, which does not. In addition, genetic elements that cannot transfer themselves can sometimes be *mobilized* or transferred during conjugation. These other genetic elements can be other plasmids or the host chromosome itself. Indeed, conjugation was discovered because the F plasmid of *Escherichia coli* can mobilize the host chromosome (see

Figure 9.27). Transfer mechanisms may differ depending on the participating plasmid, but most plasmids in gram-negative *Bacteria* employ a mechanism similar to that used by the F plasmid.

F Plasmid

The F plasmid (F stands for “fertility”) is a circular DNA molecule of 99,159 bp. Figure 9.22 shows a genetic map of the F plasmid. One region of the plasmid contains genes that regulate DNA replication. It also contains a number of transposable elements (Section 9.11) that allow the plasmid to integrate into the host chromosome. In addition, the F plasmid has a large region of DNA, the *tra* region, containing genes that encode transfer functions. Many genes in the *tra* region participate in mating pair formation, and most of these have to do with the synthesis of the conjugative pilus (◀ Section 2.6) and a type IV secretion system (◀ Section 6.13) to transfer the DNA. Only donor cells produce these pili. Different conjugative plasmids may have slightly different *tra* regions, and the pili may vary somewhat in structure. The F plasmid and its relatives encode F pili.

Pili allow specific pairing to take place between the donor and recipient cells. All conjugation in gram-negative *Bacteria* is thought to depend on cell pairing brought about by pili. The pilus makes specific contact with a receptor on the recipient cell surface and then is retracted by disassembling its subunits. This pulls the two cells

Figure 9.22 Genetic map of the F (fertility) plasmid of *Escherichia coli*. The numbers on the interior mark the size of the plasmid in kilobase pairs (the exact size is 99,159 bp). The region in dark green at the bottom of the map contains genes primarily responsible for the replication and segregation of the F plasmid. The origin of vegetative replication is *oriV*. The light green *tra* region contains the genes needed for conjugative transfer. The origin of transfer during conjugation is *oriT*. The red arrowhead at *oriT* indicates the leading edge and direction of the transfer, and the black arrow is alongside the first part of the plasmid to be transferred behind *oriT*. The *tra* region is transferred last. Insertion sequences are shown in yellow. These may recombine with identical elements on the bacterial chromosome, which leads to integration and the formation of different Hfr strains (Section 9.9). Inset: Atomic force microscopy visualization of supercoiled plasmid DNA. Modified from Witz, G. and Stasiak, A. 2010. *Nucleic Acids Res.* 38: 2119.

Figure 9.23 Visualization of conjugation. (a) Formation of a mating pair. Direct contact between two conjugating *Escherichia coli* cells is first made via a pilus. The cells are then drawn together to form a mating pair by retraction of the pilus, which is achieved by depolymerization. Certain small phages (F-specific bacteriophages) use the conjugative pilus as a receptor and can be seen here attached to the pilus. (b) Coupling proteins near the cell membrane (white arrows). These *Bacillus subtilis* cells contain the conjugative plasmid pLS20 encoding the VirD coupling protein linked to a fluorescent reporter gene. (c) Conjugation junctions. together (Figure 9.23a). Following this process, donor and recipient cells remain in contact by binding coupling proteins located in the outer membrane of each cell (Figure 9.23b). DNA is then transferred from donor to recipient cell through this conjugation junction (Figure 9.23c).

Mechanism of DNA Transfer during Conjugation

DNA synthesis is necessary for DNA transfer by conjugation—the donor cell does not lose the genes it transfers but instead makes a copy as the DNA is transferred. In this case, DNA is synthesized not by normal bidirectional replication (◀ Section 6.4) but by **rolling circle replication**, a mechanism also used by some DNA viruses (▶ Section 11.3) and shown in Figure 9.24. DNA transfer is triggered by cell-to-cell contact, at which time one strand of the circular plasmid DNA is nicked and transferred to the recipient. The nicking enzyme required to initiate the process, TraI, is encoded by the *tra* operon of the F plasmid. TraI also has helicase activity and thus unwinds the DNA strand to be transferred. As the transfer occurs, DNA synthesis by the rolling circle mechanism replaces the

transferred strand in the donor, while a complementary DNA strand is being made in the recipient. Therefore, at the end of the process, both donor and recipient possess complete plasmids. For transfer of the F plasmid, if an F-containing donor cell, which is designated F^+ , mates with a recipient cell lacking the plasmid (F^-), the result is two F^+ cells (Figure 9.24).

Transfer of plasmid DNA is efficient and rapid; under favorable conditions virtually every recipient cell that pairs with a donor acquires a plasmid. Transfer of the F plasmid (approximately 100 kbp) takes about 5 min. If plasmid genes can be expressed in the recipient, the recipient itself becomes a donor and can transfer the plasmid to other recipients. In this fashion, conjugative plasmids can spread rapidly among bacterial populations, behaving much like infectious agents. This is of major ecological significance because conjugative plasmids have been found in many *Bacteria* and some *Archaea* (Section 9.10), and a few plasmid-containing cells introduced into a population of potential recipients can convert the entire population into plasmid-bearing (and thus donating) cells in a short time.

Check Your Understanding

- In conjugation, how are donor and recipient cells brought into contact with each other?
- Explain how rolling circle DNA replication allows both donor and recipient to end up with a complete copy of a plasmid transferred by conjugation.

9.9 The Formation of Hfr Strains and Chromosome Mobilization

In addition to plasmid genes, chromosomal genes can be transferred by plasmid-mediated conjugation. As mentioned above, the F plasmid of *Escherichia coli* can, under certain circumstances, *mobilize the chromosome* for transfer during cell-to-cell contact. The F plasmid is actually an *episome*, a plasmid that can integrate into the host chromosome. When the F plasmid is integrated, chromosomal genes can be transferred along with the plasmid. Following genetic recombination between donor and recipient DNA, horizontal transfer of chromosomal genes by this mechanism can be extensive.

Cells possessing a *nonintegrated* F plasmid are called F^+ , whereas those with an F plasmid integrated into the chromosome are called **Hfr cells** (for *high frequency of recombination*). This term refers to the high rates of genetic recombination between genes on the donor (Hfr) and recipient (F^-) chromosomes. Both F^+ and Hfr cells are donors, but unlike conjugation between an F^+ and an F^- , conjugation between an Hfr donor and an F^- leads to transfer of genes from the host chromosome. This is because the chromosome and plasmid now form a single molecule of DNA. Consequently, when rolling circle replication is initiated by the F plasmid, replication continues on into the chromosome. Thus, the chromosome is also replicated and parts of it get transferred. Hence, integration of a conjugative plasmid provides the mechanism for mobilizing a cell's genome.

Overall, the presence of the F plasmid results in three distinct changes in a cell: (1) the ability to synthesize the F pilus (Figure 9.23a), (2) the mobilization of DNA for transfer to another cell, and (3) the

Figure 9.24 Transfer of plasmid DNA by conjugation. (a) Transfer of the F plasmid converts an F⁻ recipient cell into an F⁺ cell. Note the mechanism of rolling circle replication in steps 4 and 5. (b) Details of the replication and transfer process. Note the large number of proteins needed for successful DNA transfer. (c) Visualization of DNA transfer by conjugation in *Bacillus subtilis* using fluorescence microscopy. The donor cell constitutively expresses a red fluorescent protein, while the recipient cells fluoresce green due to green fluorescent protein (GFP) fused to LacI. The DNA transferred from the donor contains a *lacO* operator region that binds LacI-GFP. Arrow indicates focal point in the recipient cell where LacI-GFP is bound to the *lacO* region obtained from conjugation. The *lac* operon is discussed in Sections 7.3 and 7.8.

alteration of surface receptors so the cell can no longer be a recipient in conjugation and is therefore unable to take up a second copy of the F plasmid or any genetically related plasmids.

Integration of F Plasmid and Chromosome Mobilization

The F plasmid and the chromosome of *E. coli* both carry several copies of mobile genetic elements called *insertion sequences* (ISs; Section 9.11). These provide regions of sequence homology between chromosomal and F plasmid DNA. Consequently,

homologous recombination between an IS on the F plasmid and a corresponding IS on the chromosome results in integration of the F plasmid into the host chromosome (Figure 9.25). Once integrated, the plasmid no longer replicates independently, but the *tra* operon still functions normally and the Hfr strain synthesizes pili (Figure 9.23). When a recipient cell is encountered, conjugation is triggered just as in an F⁺ cell, and DNA transfer is initiated at the *oriT* (origin of transfer) site. However, because the plasmid is now part of the chromosome, after part of the plasmid DNA is

Figure 9.25 The formation of an Hfr strain. Integration of the F plasmid into the chromosome may occur at a variety of specific sites where IS elements are located. The example shown here is an IS3 located between the chromosomal genes *pro* and *lac*. Some of the genes on the F plasmid are shown. The arrow indicates the origin of transfer, *oriT*, with the arrow as the leading end. Thus, in this Hfr, *pro* would be the first chromosomal gene to be transferred and *lac* would be among the last.

transferred, chromosomal genes begin to be transferred (Figure 9.26). As in the case of conjugation with just the F plasmid itself (Figure 9.24), chromosomal transfer also requires DNA replication.

Because the DNA strand usually breaks during transfer, only part of the donor chromosome is typically transferred. Consequently, the recipient does not become Hfr (or F^+) because only part of the integrated F plasmid is transferred (Figure 9.27). However, after transfer, the Hfr strain remains genetically Hfr because it retains a copy of the integrated F plasmid. Following recombination, the recipient cell may express a new phenotype due to the incorporation of donor genes, but genetically it remains an F^- cell.

Figure 9.26 Transfer of chromosomal genes by an Hfr strain. The Hfr chromosome breaks at the origin of transfer within the integrated F plasmid. The transfer of DNA to the recipient begins at this point. DNA replicates during transfer as for a free F plasmid (Figure 9.24). This figure is not to scale; the inserted F plasmid is actually less than 3% of the size of the *Escherichia coli* chromosome.

Figure 9.27 Transfer of chromosomal DNA by conjugation. Transfer of the integrated F plasmid from an Hfr strain results in the cotransfer of chromosomal DNA because it is linked to the plasmid. The steps in transfer are similar to those shown in Figure 9.24a. However, the recipient remains F^- and receives a linear fragment of donor chromosome attached to part of the F plasmid. For donor DNA to survive, it must be recombined into the recipient chromosome after transfer (not shown).

Because a partial chromosome cannot replicate, for incoming donor DNA to survive, it must recombine with the recipient chromosome. As in transformation and transduction, genetic recombination between donor and recipient genes requires homologous recombination (Figure 9.12) in the recipient cell.

Because several distinct insertion sequences are present on the *E. coli* chromosome, a number of different Hfr strains are possible. A given Hfr strain always donates genes in the same order, beginning at the same position. However, Hfr strains that differ in the chromosomal integration site of the F plasmid transfer their genes in different orders (Figure 9.28). At some insertion sites, the F plasmid is integrated with its origin pointing in one direction, whereas at other sites the origin points in the opposite direction. The orientation of the F plasmid determines which chromosomal genes enter the recipient cell first, illustrating how virtually any gene on the chromosome can be mobilized by one Hfr configuration or another (Figure 9.28).

Transfer of Chromosomal Genes to the F Plasmid

Occasionally, integrated F plasmids may be excised from the chromosome. During excision, chromosomal genes may sometimes be

Figure 9.28 Formation of different Hfr strains. Different Hfr strains donate genes from different origins and thus genes are transferred in different orders. (a) F plasmids can be inserted into various insertion sequences on the bacterial chromosome, forming different Hfr strains. (b) Order of gene transfer for different Hfr strains. See Figures 9.25–9.27 for details of Hfr formation and DNA transfer.

incorporated into the liberated F plasmid. This can happen because both the F plasmid and the chromosome contain multiple identical insertion sequences where recombination can occur (Figure 9.25). F plasmids containing chromosomal genes are called *F'* (F-prime) *plasmids*. When *F'* plasmids promote conjugation, they transfer the chromosomal genes they carry at high frequency to the recipients. *F'*-mediated transfer resembles specialized transduction (Section 9.7) in that only a restricted group of chromosomal genes is transferred by any given *F'* plasmid. Transferring a known *F'* into a recipient allows one to establish diploids (two copies of each gene) for a limited region of the chromosome. Such partial diploids (merodiploids) are useful for genetic complementation experiments (Section 9.5).

We segue now to the final part of this chapter in which we explore archaeal genetics, movable genetic elements, and a major mechanism prokaryotic cells have evolved to protect their genomic integrity, a mechanism that has been exploited to revolutionize biology.

Check Your Understanding

III • Gene Transfer in *Archaea* and Other Genetic Events

Although phylogenetically distinct from *Bacteria*, *Archaea* have evolved similar mechanisms for horizontal gene transfer. Some genetic elements can move about the chromosome, and a host of surveillance systems are present in prokaryotic cells that function to “search and destroy” foreign DNA.

Although studies of the genetics of *Archaea* lag behind genetics research in *Bacteria*, they are showing progress, along with the development of archaeal versions of the tools necessary for detailed genetic analyses. In addition, some other genetic events in *Bacteria* reveal important genetic concepts even though they do not involve horizontal gene flow per se. These events can trigger genomic duplications and rearrangements, which increase genetic diversity (Chapter 13).

9.10 Horizontal Gene Transfer in *Archaea*

Although *Archaea* contain a single circular chromosome (Figure 9.29), as do most *Bacteria* (Section 6.2), and genome analysis clearly shows that horizontal transfer of archaeal DNA occurs in nature, experimental gene transfer systems are not as well developed for *Archaea* as they are for *Bacteria*. Some reasons for this are of a practical nature including the fact that most well-studied *Archaea* are extremophiles, capable of growth only under conditions of high salt or high temperature (Chapter 17). The temperatures necessary to culture some hyperthermophiles, for example, will melt agar, and alternative materials are required to form solid media and obtain colonies.

Another problem is that most known antibiotics do not affect *Archaea*. For example, penicillins do not affect *Archaea* because their cell walls lack peptidoglycan. The choice of selectable markers for use in genetic crosses is therefore often limited. However, novobiocin (a DNA gyrase inhibitor) and mevinolin (an inhibitor of isoprenoid biosynthesis) have been used to inhibit growth of extreme halophiles, and puromycin and neomycin (both protein

Figure 9.29 An archaeal chromosome, as shown by transmission electron microscopy. The circular chromosome is from the hyperthermophile *Sulfolobus*, a member of the *Archaea*.

synthesis inhibitors) inhibit methanogens. Auxotrophic strains (Section 9.1) of a few *Archaea* have also been isolated for genetic selection purposes.

Examples of Archaeal Genetics

No single species of *Archaea* has become a model organism for archaeal genetics, although more genetic work has been done on select species of extreme halophiles (*Halobacterium*, *Haloferax*, ► Section 17.1) than on any other *Archaea*. Various mechanisms of gene transfer have been discovered in select species of *Archaea*, including transformation, transduction, and conjugation. In addition, several plasmids are known and some have been used to construct cloning vectors, allowing genetic analysis through gene cloning and sequencing rather than through traditional genetic means, such as genetic crosses (Section 9.5). Transposon mutagenesis (Section 9.11) has been well developed in certain methanogens, including species of *Methanococcus* and *Methanosarcina*, and other tools such as shuttle vectors and other in vitro methods of genetic analysis (Chapter 12) have been developed for study of the unique biochemistry of the methanogens (► Sections 14.15 and 17.2).

Archaeal Competence and Viral Transfer

Transformation occurs in the methanogen *Methanococcus voltae* and the hyperthermophiles *Thermococcus kodakarensis* and *Pyrococcus furiosus*, all of which are naturally competent (Section 9.6). Intraspecies exchange of plasmids occurs in some species of *Thermococcus* and *Halorubrum* through the budding of the cell envelope, a process that results in DNA-containing membrane vesicles as vehicles of genetic exchange. Formation of membrane vesicles occurs in species of all three domains of life, and these structures can carry both protein and nucleic acid. While DNA transfer by membrane vesicles has also been observed in *Bacteria*, the mechanism observed in transferring the pR1SE plasmid by the extreme halophile *Halorubrum lacusprofundi* blurs the line between transformation and transduction. While pR1SE does not encode genes of viral origin, the plasmid does contain genes encoding membrane proteins that are inserted into the host's membrane; these are then used to form regularly shaped membrane vesicles that function to transfer the plasmid between cells (Figure 9.30). Thus, pR1SE mimics a virus because the genetic element encodes a portion of a structurally defined particle that transfers the plasmid between *H. lacusprofundi* strains.

Other conditions for transformation work reasonably well in several *Archaea* although the details vary from organism to organism. One approach requires removal of divalent metal ions, which in turn results in the partial disassembly of the glycoprotein cell wall layer that surrounds many archaeal cells (the S-layer, ◀ Section 2.5), and this allows access to transforming DNA. However, *Archaea* with rigid cell walls have proven difficult to transform, although electroporation (Section 9.6) sometimes works. One exception is in *Methanosarcina* species, organisms with a thick polysaccharide cell wall (► Section 17.2). In this organism, a high-efficiency transformation system has been developed that employs DNA-loaded lipid preparations (liposomes) that are able to traverse the cell wall and deliver DNA into the cell.

Although viruses that infect *Archaea* are plentiful, transduction is rare. Only one archaeal virus, which infects the thermophilic

Figure 9.30 Membrane vesicles and plasmid transfer in *Halorubrum lacusprofundi* R1S1. (a) Transmission electron micrograph showing an isolated cell with membrane vesicles budding from the cell surface. Filaments around the cell are cell appendages and archaella. (b) Membrane vesicles containing plasmid DNA isolated from the supernatant of R1S1 cells. Each vesicle is 80–110 nm in diameter. methanogen *Methanothermobacter thermautotrophicus*, has been shown to transduce host genes. Unfortunately, the low burst size (about six phage virions liberated per cell) makes it impractical to use this system for gene transfer. Gene transfer agents (Section 9.7) have been found in one species of methanogen but do not appear to be widespread in *Archaea*.

Transfer by Cell-to-Cell Contact

Different types of conjugation have been detected in *Archaea*. Some strains of the thermophilic and acidophilic *Sulfolobus solfataricus* (► Section 17.10) contain plasmids that promote conjugation between two cells in a manner similar to that seen in *Bacteria*. In this process, cell pairing is independent of pili formation, but as for *Bacteria*, DNA transfer is unidirectional. However, most of the genes encoding conjugation in *S. solfataricus* have little similarity to those in gram-negative *Bacteria*. An exception is a gene similar to the gene *traG* located on the *Escherichia coli* F plasmid (Sections 9.8 and 9.9); the protein product of the archaeal version of this gene participates in stabilizing mating pairs. Thus it is likely that the overall mechanism of conjugation in *Archaea* differs in significant ways from that in *Bacteria*.

Most species of *Sulfolobus* can also exchange DNA without the participation of a fertility plasmid. Such exchange is dependent on cell aggregation, a process that requires pili whose synthesis is triggered by UV radiation. While the exact mechanism of this unusual DNA exchange is unknown, these pili bring cells of the same species together through recognition of S-layer glycosylation patterns present on the cell walls.

Other *Archaea* form specialized structures between cells that allow for genetic exchange, and the formation of these structures is also independent of a fertility plasmid. For example, Figure 9.31 illustrates the formation of DNA-transferring nanotubes between cells of a *Thermococcus* species. Interestingly, unlike the other means of horizontal gene transfer discussed in this chapter, the *Thermococcus*

Evelyn Marguet and Patrick Forterre

Figure 9.31 Nanotubes and *Thermococcus*. Scanning electron micrograph showing nanotubes linking cells of a species of *Thermococcus*. A single *Thermococcus* cell is about 1 μm in diameter.

nanotubes allow for *bidirectional* transfer of DNA. Thus, with both cells in an exchange able to function as recipients, the *Thermococcus* nanotubes likely facilitate very dynamic gene flow. Similarly, some halobacteria also form cytoplasmic bridges between mating cells that are used for DNA transfer. Although the nanotube and cytoplasmic bridge systems are not yet routine laboratory tools, they may well prove useful for the future development of more facile archaeal genetic transfer systems.

Check Your Understanding

- Why is it usually more difficult to select recombinants with *Archaea* than with *Bacteria*?
- Why do penicillins not kill species of *Archaea*?

9.11 Mobile DNA: Transposable Elements

As we have seen, molecules of DNA may move from one cell to another, but to a geneticist, the phrase “mobile DNA” has a special meaning. Mobile DNA refers to discrete segments of DNA that move as units from one location to another *within* other DNA molecules.

Although the DNA of certain viruses can be inserted into and excised from the genome of the host cell (◀ Section 5.6 and ▶ Section 11.4), most mobile DNA consists of **transposable elements**. These are stretches of DNA that can move from one site to another. However, transposable elements are always found inserted into another DNA molecule such as a plasmid, a chromosome, or a viral genome. Transposable elements do not possess their own origin of replication. Instead, they are replicated when the host DNA molecule into which they are inserted is replicated.

Transposable elements move by *transposition*, a process that is important in both genome rearrangement and genetic analysis. Transposable elements are extremely abundant and widespread in nature and are present in the genomes of all three domains of life and in many viruses and plasmids, suggesting that the elements offer a selective advantage by accelerating genome rearrangement and gene duplication (▶ Section 13.8).

The two major types of transposable elements in *Bacteria* are *insertion sequences* (ISs) and *transposons*. Both elements have two

important features in common: They carry genes encoding *transposase*, the enzyme necessary for transposition, and they have short inverted terminal repeats at their ends that are also needed for transposition (the ends of transposable elements are not free but are continuous with the host DNA molecule into which the transposable element has inserted). **Figure 9.32** shows genetic maps of two well-studied transposable elements: the insertion element IS2 and the transposon Tn5.

Insertion Sequences and Transposons

Insertion sequences (ISs) are the simplest type of transposable element. They are short DNA segments, about 1000 nucleotides long, and typically contain inverted repeats of 10–50 base pairs. Each different IS has a specific number of base pairs in its terminal repeats, and the only protein encoded is the transposase. Several hundred distinct IS elements have been characterized. IS elements are found in the chromosomes and plasmids of both *Bacteria* and *Archaea*, as well as in certain bacteriophages. Individual strains of the same bacterial species vary in the number and location of the IS elements they harbor. For instance, the genome of one strain of *Escherichia coli* has five copies of IS2 and five copies of IS3. Many plasmids, such as the F plasmid, also carry IS elements. Indeed, integration of the F plasmid into the *E. coli* chromosome is facilitated by recombination between identical IS elements on the F plasmid and the chromosome (Section 9.9 and Figure 9.25).

Transposons are larger than IS elements but have the same two essential components: inverted repeats at both ends and a gene encoding the transposase (Figure 9.32b). The transposase recognizes the inverted repeats and moves the segment of DNA flanked by them from one site to another. Consequently, any DNA that lies between the two inverted repeats is moved and is, in effect, part of the transposon. Genes included inside transposons vary widely. Some of these genes, such as antibiotic resistance genes, confer important new properties on the organism. Because antibiotic resistance is both important and easy to detect, most well-studied transposons

Figure 9.32 Maps of the transposable elements IS2 and Tn5. The arrows above the maps show the direction of transcription of any genes on the elements. The gene encoding the transposase is *tnp*. (a) IS2 is an insertion sequence of 1327 bp with inverted repeats of 41 bp at its ends. (b) Tn5 is a composite transposon of 5.7 kbp containing the insertion sequences IS50L and IS50R at its left and right ends, respectively. IS50L is not capable of independent transposition because there is a nonsense mutation, marked by a blue cross, in its transposase gene. The genes *kan*, *str*, and *bleo* confer resistance to the antibiotics kanamycin (and neomycin), streptomycin, and bleomycin.

Figure 9.33 Transposition. (a) Insertion of a transposable element generates a duplication of the target sequence. Note the presence of inverted repeats (IR) at the ends of the transposable element. (b) Two mechanisms of transposition. Donor DNA (carrying the transposon) is shown in green, and recipient DNA carrying the target sequence is shown in yellow. In both conservative and replicative transposition, the transposase inserts the transposon (purple) into the target site (red) on the recipient DNA. During this process, the target site is duplicated. In conservative transposition, the donor DNA is left with a double-stranded break at the previous location of the transposon. In contrast, after replicative transposition, both donor and recipient DNA possess a copy of the transposon.

contain antibiotic resistance genes as selectable markers. Examples include transposon Tn5, which encodes resistance to the antibiotics kanamycin (and neomycin), streptomycin, and bleomycin (Figure 9.32b), and Tn10, which encodes tetracycline resistance.

Because any genes lying between the inverted repeats become part of a transposon, it is possible to get hybrid transposons that display complex behavior. For example, conjugative transposons contain *tra* genes (Figures 9.25 and 9.26) and can therefore move between bacterial species by conjugation as well as transpose from place to place within a bacterial genome.

Mechanisms of Transposition

Both the inverted repeats (located at the ends of transposable elements) and transposase are essential for transposition. The transposase recognizes, cuts, and ligates the DNA during transposition. When a transposable element is inserted into target DNA, a short sequence in the target DNA at the site of integration is duplicated during the insertion process (Figure 9.33a). The duplication arises because single-stranded DNA breaks are made by the transposase. The transposable element is then attached to the single-stranded

ends that have been generated. Finally, enzymes of the host cell repair the single-strand portions, which results in the duplication.

Two mechanisms of transposition are known: conservative and replicative (Figure 9.33b). In *conservative* transposition, as occurs with the transposon Tn5 (Figure 9.32b), the transposon is excised from one location and reinserted at a second location. The copy number of a conservative transposon therefore remains at one. By contrast, during *replicative* transposition, a new copy of the transposon is produced and inserted at the second location. Thus, after a replicative transposition event, one copy of the transposon remains at the original site, while a second copy is incorporated at the new site.

Utility of Transposon Mutagenesis

When a transposon inserts itself within a gene, the DNA sequence in the gene is altered and a mutation occurs (Figure 9.34). Mutations due to transposon insertion do occur naturally. However, laboratory use of transposons has been a powerful genetic tool to create a library of bacterial mutants. To do this, transposons carrying antibiotic resistance genes are used. With conjugation or transformation

Figure 9.34 Transposon mutagenesis. The transposon moves into the middle of gene 2. Gene 2 is now disrupted by the transposon and is inactivated. Gene A from the transposon is now expressed from the chromosome.

as the transfer mechanism, the transposon is introduced into the target cell on a plasmid that cannot replicate in that particular host. Consequently, antibiotic-resistant colonies will mostly be due to insertion of the transposon into the bacterial genome.

Because bacterial genomes contain relatively little noncoding DNA, most transposon insertions will occur in genes that encode proteins. This technique can be used to determine the function of a novel gene if a screening method is available. For example, if a transposon inserts into a gene encoding a product required for biofilm formation (biofilms are colonies of microbes encased in an adhesive and attached to a surface, ◀ Section 4.9), the transposon mutant will no longer grow in the biofilm mode. Then, further genetic analyses can be performed to reveal which gene the transposon has disrupted. **Figure 9.35** illustrates the use of transposon mutagenesis to study flagella structure and function in a notorious biofilm-producing bacterium, *Pseudomonas aeruginosa* (◀ Section 8.10). In this research, transposon mutagenesis combined with a special staining technique was used to identify the protein FlgK of the flagellar hook (◀ Section 2.9) as a protein required for biofilm formation.

Two transposons widely used for mutagenesis of *E. coli* and related bacteria are Tn5 (Figure 9.32b) and Tn10. Many *Bacteria*, a few *Archaea*, and the yeast *Saccharomyces cerevisiae* have all been mutagenized using genetically engineered transposons. In Chapter 10 we

Figure 9.35 Utility of transposon mutagenesis. A transposon (Tn) conferring kanamycin resistance (Km^R) is added to a culture of wild-type *Pseudomonas aeruginosa*. After selection for integration of the transposon using the antibiotic kanamycin, the mutants are screened for biofilm formation in a microtiter plate. Cultures that produce biofilm adhere to the microtiter plate (ring in left tube of inset photo) and the resulting biofilm can be stained with crystal violet. Primers specific to the Tn can be used to determine the Tn insertion site and the identity of the interrupted gene. *flgK* encodes a protein in the flagellar hook.

will learn about how engineered transposons can be used in metagenomic studies to determine the role of individual genes in a microbe's overall fitness. More recently, transposons have even been used to isolate mutations in animals, including mice.

We finish this chapter with a consideration of genomic stability (in contrast to the genomic alterations we have discussed thus far) and preview the application of this process to biotechnology and synthetic biology.

- How can transposons be used in bacterial genetics?

9.12 Preserving Genomic Integrity and CRISPR

While DNA transfer is key to the diversity and evolution of *Bacteria* and *Archaea*, cells also have mechanisms to prevent horizontal gene transfer and viral infection from occurring. With viruses outnumbering prokaryotic cells in nature by a factor of 10, barriers against gene transfer are key to preserving genome integrity and ultimately species maintenance. **Figure 9.36** provides an overview of gene transfer barriers that work in concert in both *Bacteria* and *Archaea*. While our focus here is on mechanisms to prevent DNA transfer from viruses, such as modification of viral host cell receptors (◀ Section 5.5 and Figure 9.36), these barriers also target incoming naked and plasmid DNA.

Because barriers to horizontal gene transfer must distinguish invading DNA from self DNA, and protect the latter, they are considered bacterial and archaeal *immune systems*. Thus, processes that are *nonspecific* are considered analogous to *innate immunity* (Chapter 26), whereas mechanisms that target *specific* incoming nucleic acid are considered a form of *adaptive immunity* (Chapter 27). Despite engaging these forms of bacterial and archaeal immunity, the relationship between viruses and their bacterial and archaeal hosts is not static but instead extremely dynamic. That is, although microbial cells possess several weapons to battle viral attack, viruses counter these immune systems with weapons of their own, triggering a microbial “arms race” for cell survival and viral propagation.

Bacterial and Archaeal Innate Immunity

In our discussion of viruses in Section 5.5, we briefly considered restriction endonucleases—proteins produced by both *Bacteria* and *Archaea* that target and destroy foreign DNA—and how these enzymes protect the cell from viral attack. Restriction enzymes also target foreign DNA entering the cell as a result of transformation and conjugation events (Figure 9.36). The cell's DNA is protected from its own restriction endonucleases because the enzymes' recognition sequences are chemically modified (▶ Section 12.2). As we mentioned in Chapter 5, some viruses avoid restriction endonuclease surveillance by modifying their DNA to mimic the chemical

Figure 9.36 Barriers to horizontal gene transfer in *Bacteria* and *Archaea* using phage infection as an example. Some possible outcomes of viral attack: (a) Successful viral infection. (b) The virus is prevented from recognizing and binding to its host cell; viral DNA cannot enter. (c) The foreign DNA is degraded by host cell restriction endonucleases (host cell DNA is not degraded because it is chemically modified at restriction cut sites). (d) The foreign DNA is modified by the host cell's replication machinery such that it is not replicated. (e) Programmed cell death kills the host and thus prevents successful infection. (f) CRISPR activity destroys foreign DNA: crRNAs and Cas proteins detect DNA as previous invading DNA and degrade it through nuclease activity. Abbreviations: RE, restriction endonuclease; ME, modification enzyme; crRNA, CRISPR (clustered regularly interspaced short palindromic repeat) RNA; Cas (CRISPR-associated) protein.

modification found in the host genome. In response, some bacteria have evolved altered restriction enzyme systems that recognize this viral DNA modification and still degrade the incoming viral DNA, preventing viral infection.

An example of this microbial arms race is that of T4 bacteriophage and its host cell *Escherichia coli*. The adaptation of *E. coli* recognizing modified phage DNA has now selected for T4 bacteriophages that modify their DNA in a different manner—by glycosylating (adding sugars) to specific DNA bases. Then, as one might expect in an expanding arms race, some strains of *E. coli* have evolved restriction systems that recognize glycosylated viral DNA and destroy it. As a countermeasure to this, some T4 strains have evolved a protein that inhibits these modified restriction enzymes. In a constant attempt to stay ahead, other *E. coli* strains have evolved endonucleases that are not inhibited by these bacteriophage proteins, and so it goes, back and forth as both predator and prey fight to survive and propagate in the face of “the enemy.”

Recent studies have uncovered yet additional mechanisms for thwarting viral infection, such as the *phage exclusion* and *abortive infection* systems present in both *Bacteria* and *Archaea* (Figure 9.36). Phage exclusion systems are a variant of restriction enzyme systems. Genes of the phage exclusion system encode enzymes that recognize and then modify incoming foreign DNA so that it cannot be replicated; this modification results in replication of only the host cell's

DNA and not the modified DNA. In contrast, abortive infection systems trigger the host cell to commit suicide (Figure 9.36). These systems are encoded by toxin–antitoxin systems (◀ Section 8.12) that result in *programmed cell death*. Although the host cell dies during this abortive infection, its death prevents more virions from being produced and released to infect other cells in the population, thereby increasing the survival rate in the host population.

Adaptive Immunity and CRISPR

A major antiviral defense system present in both *Bacteria* and *Archaea* is CRISPR—clustered regularly interspaced short palindromic repeats—which functions to seek out and destroy foreign nucleic acid. While some CRISPR systems can target RNA viruses, our discussion will focus on systems that target foreign DNA. Besides protecting against viral infection, CRISPR also helps the cell maintain the stability and integrity of its genome by destroying certain plasmids and other genes obtained from horizontal transfers.

CRISPR regions are short repeats of *constant* DNA sequence present on the host chromosome that alternate with short *variable* DNA sequences called *spacers* (Figure 9.37). Spacers correspond to sequences of viral or other foreign DNA and function as a “memory bank” of past encounters with a virus in a manner reminiscent of how animals produce antibodies and long-lasting memory cells

Figure 9.37 CRISPR defense system against viruses and foreign DNA. (a) Immunization. Incoming viral DNA is targeted by the memorizing complex of Cas proteins. This complex selects a protospacer region based on protospacer adjacent motif (PAM) sequences located on the viral genome. Once the protospacer is excised from the viral genome, the memorizing complex inserts

the protospacer into the CRISPR region of the chromosome, resulting in a unique spacer region. (b) Interference. The chromosomal CRISPR region is transcribed and processed by Cas proteins into crRNAs that correspond to the individual spacer regions. Each spacer segment corresponds to previous encounters with incoming foreign nucleic acid. Cas proteins bind to

these crRNAs and search for complementary DNA. If a crRNA binds to the DNA of an invading virus, forming a crRNA:DNA duplex, the endonuclease activity of the cleavage complex is triggered and results in the degradation of incoming viral DNA.

against an infecting virus. Because of this specificity, the CRISPR system is analogous to the adaptive immune response of vertebrate animals (Chapter 27).

Besides the spacer regions, another essential component of the CRISPR system is the *Cas* (CRISPR-associated) proteins. These proteins possess endonuclease activity and both mediate the defense against foreign DNA and incorporate new spacers into the CRISPR region. When a virus attaches to a host cell and injects its DNA, the Cas proteins of a CRISPR region may recognize specific DNA sequences known as *protospacer adjacent motifs* (PAMs) (Figure 9.37a). The Cas protein then cleaves the viral DNA at a locus near this PAM (termed the *protospacer*) and inserts the short DNA region into the CRISPR region of the chromosome, where it becomes a *spacer* (Figure 9.37a). The insertion of a spacer into the CRISPR region confers “genetic memory” (referred to as *immunization*) on the cell and sets the stage for later encounters with the same virus.

When an immunized cell encounters the same virus later, the Cas proteins quickly destroy the incoming DNA in an RNA-dependent process. While the genomic CRISPR region does not contain open

reading frames, it does have a promoter (◀ Section 6.5). The resulting transcript is considered the *pre-CRISPR RNA* (pre-crRNA) and contains an array of RNA sequences complementary to both the repeat and spacer regions. The Cas proteins then process the transcript into individual spacer RNAs by targeting the repeat regions (Figure 9.37b). These crRNAs then associate with Cas proteins within the cleavage complex and begin surveillance for complementary incoming viral DNAs. Any viral DNA:crRNA duplexes formed are cleaved by the endonuclease activity of Cas proteins, and the invading DNA is degraded in a process called *interference* (Figure 9.37b). With part of its DNA destroyed in this way, the foreign DNA molecule of an invading virus cannot proceed to replicate and the infection (and threat to the cell) is thwarted.

One of the major conundrums of the CRISPR system is how a host can survive the *initial* viral invasion long enough to become immunized. For the CRISPR system to successfully prevent viral infection, a spacer corresponding to a region of the viral genome must already be present in the CRISPR locus. Immunization probably occurs when an incoming virus has been inactivated by environmental

factors (such as ultraviolet radiation) or when the host's restriction enzyme system cleaves the invading DNA before a successful infection can be initiated.

Distribution of CRISPR Systems and Anti-CRISPR Systems

CRISPR systems are widely distributed in both *Archaea* and *Bacteria*. Approximately 90% of the sequenced genomes of *Archaea* and 70% of those of *Bacteria* possess a CRISPR system. The utility of the system was first demonstrated in the dairy industry where starter cultures used for milk fermentation were susceptible to rampant bacteriophage infection. However, a strain of *Streptococcus thermophilus* was found to be resistant to virulent bacteriophage, and the difference between this *S. thermophilus* strain and those susceptible to viral infection was the spacers within its CRISPR region.

Because of the dynamic nature of the phage–host interaction, viruses have evolved mechanisms to avoid CRISPR surveillance and destruction. These include mutation of the PAM regions recognized by the memorizing complex of Cas proteins and the production of proteins that inhibit activity of the cleavage complex of Cas proteins (Figure 9.37b). This illustrates how the CRISPR system—central as it may be to preventing attacks on a cell's genome—does have a drawback in its reliance on recognizing previously encountered DNA sequences that can continue to mutate in their host and then reappear in the future in a form not recognized by CRISPR.

In addition, a phage-encoded (in contrast to cell-encoded) CRISPR system has been identified in the genome of a bacteriophage that infects *Vibrio cholerae*, the bacterium that causes cholera. The phage-encoded crRNAs target genes in *V. cholerae* that encode a defense system that prevents bacteriophage propagation; when these genes are inactivated, the cell's defense system is inoperative, a rather elaborate example of the “arms race” between bacteria and their viruses.

While CRISPRs are a major weapon *Bacteria* and *Archaea* have evolved for viral surveillance and maintaining genomic integrity, the mechanisms employed by CRISPR/Cas have not been overlooked by the scientific community. In Chapter 12 we discuss how the CRISPR/Cas system has been exploited as a powerful tool for synthetic biology and has opened up the possibility of radically new therapeutic strategies for human medicine (► Section 12.13).

CHAPTER REVIEW

I • Mutation

- 9.1** Mutation is a heritable change in the nucleotide sequence of the genome and may lead to a change in phenotype. Selectable mutations are those that give the mutant a growth advantage under certain environmental conditions and are especially useful in genetic research. If selection is not possible, mutants must be identified by screening.

Q Write a one-sentence definition of the term “genotype.” Do the same for “phenotype.” Does the phenotype of an organism automatically change when a change in genotype occurs? Why or why not? Can phenotype change without a change in genotype? In both cases, give examples to support your answer.

- 9.2** Mutations, either spontaneous or induced, are in the base sequence of the nucleic acid in a genome. A point mutation is due to a single base-pair change. In a nonsense mutation, the codon becomes a stop codon and an incomplete polypeptide is made. Deletions and insertions cause more dramatic changes in the DNA, including frameshift mutations that often result in complete loss of gene function.

Q What are point mutations? How do silent mutations differ from missense and nonsense mutations?

- 9.3** Different types of mutations occur at different frequencies. For a typical bacterium, mutation rates of 10^{-6} to 10^{-7} per kilobase pair are generally seen. Although RNA and DNA polymerases introduce sequence errors at about the same rate, RNA genomes typically accumulate mutations at much higher frequencies than DNA genomes.

Q What is a revertant? Explain the two common types of revertants.

- 9.4** Mutagens are chemical, physical, or biological agents that increase the mutation rate. Mutagens can alter DNA in many different ways. However, alterations in DNA are not mutations unless they are inherited. Some DNA damage can lead to cell death if not repaired, and both error-prone and high-fidelity DNA repair systems exist.

Q Explain the primary mechanisms of each of the three types of mutagens.

II • Gene Transfer in *Bacteria*

- 9.5** Homologous recombination occurs when closely related DNA sequences from two distinct genetic elements are combined together in a single element. Recombination is an

important evolutionary process, and cells have specific mechanisms for ensuring that recombination takes place.

Q What are heteroduplex regions of DNA, and what process leads to their formation?

- 9.6** Certain bacteria exhibit competence, a state in which cells are able to take up free DNA released by other bacteria, a process called transformation. Once this DNA has been taken up, typically through the action of pili, incorporation of donor DNA into a recipient cell requires the activity of the single-strand binding protein RecA and several other enzymes. Only competent cells are transformable.

Q Explain why recipient cells do not successfully take up plasmids during natural transformation.

- 9.7** Transduction is the transfer of host genes from one bacterium to another by a bacterial virus. In generalized transduction, defective virus particles randomly incorporate fragments of the cell's chromosomal DNA, but the transducing efficiency is low. In specialized transduction, the DNA of a temperate virus excises incorrectly and takes adjacent host genes along with it; the transducing efficiency here may be very high.

Q Explain how a generalized transducing particle differs from a specialized transducing particle.

- 9.8** Conjugation is a mechanism of DNA transfer in *Bacteria* and *Archaea* that requires cell-to-cell contact. Conjugation is controlled by genes carried by certain plasmids (such as the F plasmid) and requires transfer of the plasmid from a donor cell to a recipient cell. Plasmid DNA transfer requires replication using the rolling circle mechanism.

Q What is a conjugative pilus and which cell type, F^- or F^+ , would produce this structure?

- 9.9** The donor cell chromosome can be mobilized for transfer to a recipient cell. This requires an F plasmid to integrate into the chromosome to form the Hfr phenotype. Because transfer of the integrated F plasmid is rarely complete, recipient cells rarely become F^+ . F' plasmids are previously integrated F plasmids that have excised and captured some chromosomal genes.

Q What is a merodiploid, and how does an F' plasmid yield a merodiploid?

III • Gene Transfer in *Archaea* and Other Genetic Events

- 9.10** Archaeal research lags behind bacterial research in the development of systems for gene transfer. Many antibiotics are ineffective against *Archaea*, making it difficult to select recombinants effectively, and the unusual growth conditions needed by many *Archaea* also make genetic experimentation challenging. Nevertheless, the genetic transfer systems of *Bacteria*—transformation, transduction, and conjugation—are all known in *Archaea*.

Q Explain one type of conjugation in *Archaea* and how it differs from F-plasmid-mediated conjugation.

- 9.11** Transposons and insertion sequences are genetic elements that can move from one location on a host DNA molecule to another by transposition. Transposition can be either replicative or conservative. Transposons often carry genes encoding antibiotic resistance and can be used to identify the functions of unknown genes.

Q What are the major differences between insertion sequences and transposons?

- 9.12** Bacterial and archaeal cells employ various mechanisms to prevent gene transfer and viral infection. However, the fast mutation rate of viruses allows them to adapt to these strategies. The clustered regularly interspaced short palindromic repeat (CRISPR) system is an RNA-based immune system that protects the genome of *Bacteria* and *Archaea* from invading DNA resulting from viral infection or conjugation. If small RNA molecules resulting from the spacer regions of the CRISPR region bind to incoming complementary DNA, Cas proteins destroy the nucleic acid duplex.

Q Explain why incoming DNA recognized by a short RNA molecule expressed from the CRISPR region cannot be completely foreign to the cell.

APPLICATION QUESTIONS

1. A constitutive mutant is a strain that continuously makes a protein that is inducible in the wild type. Describe two ways in which a change in a DNA molecule could lead to the emergence of a constitutive mutant. How could these two types of constitutive mutants be distinguished genetically?
2. Although a large number of mutagenic chemicals are known, none is known that induces mutations in only a single gene (gene-specific mutagenesis). From what you know about mutagens, explain why it is unlikely that a gene-specific chemical mutagen will be found. How then is site-specific mutagenesis accomplished?
3. Why is it difficult in a single experiment to transfer a large number of genes to a recipient cell using transformation or transduction?
4. Transposable elements cause mutations when inserted within a gene. These elements disrupt the continuity of a gene. Introns also disrupt the continuity of a gene, yet the gene is still functional. Explain why the presence of an intron in a gene does not inactivate that gene but insertion of a transposable element does.

CHAPTER GLOSSARY

Auxotroph an organism that has developed an additional nutritional requirement compared with the wild type, often as a result of mutation

Conjugation the transfer of genes from one prokaryotic cell to another by a mechanism requiring cell-to-cell contact

Frameshift mutation a mutation in which insertion or deletion of nucleotides changes the groups of three bases in which the genetic code is read within an mRNA, usually resulting in a faulty product

Genotype the complete genetic makeup of an organism; the complete description of a cell's genetic information

Heteroduplex a DNA double helix composed of single strands from two different DNA molecules

Hfr cell a cell with the F plasmid integrated into the chromosome

Horizontal gene transfer the unidirectional transfer of genes between cells through a process uncoupled from reproduction

Induced mutation a mutation caused by external agents such as mutagenic chemicals or radiation

Insertion sequence (IS) the simplest type of transposable element, which carries only genes that participate in transposition

Missense mutation a mutation in which a single codon is altered so that one amino acid in a protein is replaced with a different amino acid

Mutagen an agent that causes mutation

Mutant an organism whose genome carries a mutation

Mutation a heritable change in the base sequence of the genome of an organism

Nonsense mutation a mutation in which the codon for an amino acid is changed to a stop codon

Phenotype the observable characteristics of an organism

Point mutation a mutation that involves a single base pair

Recombination a resorting or rearrangement of DNA fragments resulting in a new sequence

Reversion an alteration in DNA that reverses the effects of a prior mutation

Rolling circle replication a mechanism, used by some plasmids and viruses, of replicating circular DNA, which starts by nicking and unrolling one strand. For a single-stranded genome, this is preceded by using the still-circular strand as a template for DNA synthesis; for a double-stranded genome, the unrolled strand is used as a template for DNA synthesis

Screening a procedure that permits the identification of organisms by phenotype or genotype, but does not inhibit or enhance the growth of particular phenotypes or genotypes

Selection placing organisms under conditions that favor or inhibit the growth of

those with a particular phenotype or genotype

Silent mutation a change in DNA sequence that has no effect on the phenotype

SOS repair system a DNA repair system activated by DNA damage

Spontaneous mutation a mutation that occurs "naturally" without the help of mutagenic chemicals or radiation

Transduction the transfer of host cell genes from one cell to another by a virus

Transformation the transfer of bacterial genes through the uptake of free DNA from the environment

Transition a mutation in which a pyrimidine base is replaced by another pyrimidine or a purine is replaced by another purine

Transposable element a genetic element able to move (transpose) from one site to another on host DNA molecules

Transposon a type of transposable element that carries genes in addition to those required for transposition

Transversion a mutation in which a pyrimidine base is replaced by a purine or vice versa

Wild-type strain a bacterial strain isolated from nature or one used as a parent in a genetics investigation

10 Microbial Genomics and Other Omics

I Genomics 329

II Functional Omics 341

III Systems Biology 353

MICROBIOLOGYNOW

Omics Tools Unravel Mysteries of “Fettuccine” Rocks

Mammoth Hot Springs (MHS) in Yellowstone National Park (USA) displays many geochemical traits similar to those on Mars. Because of this, geomicrobiologists study these hot, oxygen-limited and sulfur-rich springs for microbial fossils whose fingerprints of life (biomarkers) could be used to detect life on other planets. The photo on the left shows filamentous microbial mats from MHS that resemble fettuccine pasta as a result of mineral encrustation. Tens of centimeters long, these streamers contain extremophilic microbes that entomb themselves in 5 millimeters of travertine (calcium carbonate) per day, a striking biomarker that can be easily observed. How are these pasta-looking rocks formed?

Using a combination of geochemical measurements, microscopy, and metagenomic, metatranscriptomic, and metaproteomic approaches, scientists have unraveled many of the mysteries surrounding the MHS streamers. These mats are dominated by the thermophilic, chemolithotrophic bacterium *Sulfurihydrogenibium yellowstonense*, which uses CO₂ and reduced sulfur as carbon and energy sources, respectively. Multi-omic data sets indicate that these remarkable cells produce pili as well as extracellular polymeric

substances to latch onto one another and form streamers in the fast-moving spring water. Once the cells have formed microbial filaments (see scanning electron micrograph on the right), proteins expressed on the surface of *S. yellowstonense* catalyze the formation of travertine over a billion times faster than it would occur abiotically.

What is the advantage of forming these mineral-encrusted filamentous streamers? By undulating within travertine ridges, *S. yellowstonense* is able to maximize its access to the minimal oxygen and sulfide—key substrates for its energy metabolism—available within MHS waters. Thus, this organism has evolved an ingenious way to optimize chemolithotrophic growth.

Besides revealing fascinating microbiology, this study illustrates the power of omics tools to characterize microbes and their physiology in natural environments. It also highlights the utility of combined omics approaches for detecting biomarkers useful for searching for life beyond Earth.

Source: Dong, Y., et al. 2019. Physiology, metabolism, and fossilization of hot-springs filamentous microbial mats. *Astrobiology* doi:10.1089/ast.2018.1965.

Traditional approaches to studying microbial physiology and biochemistry have focused on the analysis of individual biochemical pathways or molecular responses under specific conditions. While informative, this reductionist approach can only target a specific gene or subset of genes or gene products—RNAs and proteins—and fails to address the dynamic nature of microorganisms and how a network of biological molecules controls their behavior in a coordinated fashion. By contrast, “omics” is a broad discipline that integrates different methodologies to characterize and quantify large pools of biological molecules. Through the power of combining various omics, a detailed picture of an organism’s response to its environment can be generated. Because the ability to store and analyze massive amounts of biological information by computer is essential to omics, the understanding of entire biological systems is evolving in parallel with computing power and storage and retrieval capabilities.

I • Genomics

Buried within a genome sequence lies the heart of a cell's biology, and with the sequencing technology available today, microbiology—indeed all of biology—is moving ahead faster than ever as genomes unveil their secrets at a breathtaking pace.

The foundation of omics biology lies in nucleic acid and protein sequences, characteristics ultimately controlled by the cell’s genome. The **genome** is an organism’s entire complement of genetic information, including genes that encode proteins, RNAs, and regulatory sequences, as well as any noncoding DNA that may be present. The genome sequence of an organism not only reveals its genes, but also yields important clues to how the organism functions. While new omics are coined with regularity, this chapter focuses on the major omic themes of biological molecules—*genomics*, *transcriptomics*, *proteomics*, and *metabolomics*—and describes how these various pieces of the puzzle are integrated to yield important information about the biology of a single organism, or even an entire microbial community in the case of *metagenomics*, the comprehensive analysis of specific genes or genomes in an environment (Figure 10.1).

The word **genomics** refers to the discipline of mapping, sequencing, analyzing, and comparing genomes. Here we review how genomes are sequenced and some techniques used to analyze these genomes and their gene content.

10.1 Introduction to Genomics

Advances in genomics rely heavily on improvements in molecular technologies and computing power. The automation of DNA sequencing and the development of powerful computational tools for DNA and protein sequence analysis have reduced the cost and increased the speed at which genomes are analyzed. Thus the number of sequenced genomes has grown rapidly, with the major genomics bottleneck being the digestion of vast amounts of nucleic acid sequence data.

Genomics: Then and Now

The first genomes sequenced were those of small viruses over 40 years ago, and the first bacterial genome sequence was published

Figure 10.1 Utility of microbial genome sequences. A genome sequence allows for the development of omics approaches and tools for understanding, investigating, and monitoring microorganisms, both in culture and in nature. It can also provide targets for drug and vaccine design.

in 1995. Today, DNA sequences from over 125,000 *Bacteria*, *Archaea*, and viruses, as well as datasets from metagenomic projects (Section 10.7), are available in public databases such as the Genomes Online Database (GOLD; see <https://gold.jgi.doe.gov> for an up-to-date list). With the goal of using genome sequences to advance systems and ecosystems biology, the United States Department of Energy’s *Joint Genome Institute* (JGI) sponsors GOLD. The JGI has also joined the *Genomic Encyclopedia of Bacteria and Archaea* (GEBA) in an effort to expand the coverage of genome sequences across the phylogenetic tree of life (◀ Figure 1.41b). At the time of this writing, GEBA had added over 1000 new genome sequences to the databases. These genome sequences represent a phylogenetically diverse range of *Bacteria* and *Archaea*. Despite these additions, there is plenty of “space” within the genomic tree of life (◀ Figure 1.41) for new microbial genome sequencing projects. Table 10.1 lists some representative genomes from *Bacteria* and *Archaea*. The genomes of many eukaryotic organisms have also been sequenced, including the haploid human genome, which contains about 3.2 billion bp (~21,000 protein-encoding genes, Figure 10.2). As astonishing as this large number might seem, the human genome is far from the largest genome known. Of all life forms on Earth, certain plants are known to contain the largest genomes (Figure 10.2).

TABLE 10.1 Genomes of select species of <i>Bacteria</i> and <i>Archaea</i> ^a

^bE, endosymbiont; P, parasite; FL, free-living.
^cOpen reading frames. Genes encoding known proteins are included, as well as ORFs that could encode a protein greater than 100 amino acid residues. Smaller ORFs are not included unless they show similarity to a gene from another organism or unless the codon bias is typical of the organism being studied.

Figure 10.2 Genome sizes of microbial cells and higher organisms. Compare with viral genome sizes in Chapter 11 (► Figure 11.1). The flowering plant *Paris japonica* has the largest known genome, some 50 times that of humans.

What Can Genomes Tell Us?

As we will discuss throughout this chapter, modern microbiology thrives on genome sequences; indeed, little in microbiology has been left untouched by genomic sequences. Microbial genome sequencing has discovered everything from genes encoding heat-stable enzymes in microbes that thrive in boiling water (◀ Figure 4.25b) to genes that encode virulence factors in the most vicious pathogens. Genome sequencing has also been instrumental in developing microarrays for studying gene expression (Section 10.8), detecting horizontal transfer events (between microbes of different species, genera, and even phyla; Chapters 9 and 13), monitoring and diagnosing disease outbreaks (based on the presence of “signature genes” of different pathogens), discovering CRISPRs (◀ Section 9.12) and other anti-bacteriophage systems (Section 10.5), understanding metabolic pathways, and discerning the growth requirements of microbes that have thus far defied laboratory culture.

The ability to sequence genomes has also been used to solve obscure medical mysteries. An excellent example is the genomics that revealed the causative agent of the “Black Death,” which swept through Europe in the middle of the fourteenth century (Figure 10.3a).

Figure 10.3 Diverse examples of what genomes can tell us. (a) Genomics helped solve an ancient medical mystery surrounding plague. The blackened skin on the toes of this modern plague victim originates from hemorrhaging due to systemic infection with the pathogenic bacterium *Yersinia pestis*, shown in inset. (b) Genome sequencing was used to assign the marine ammonia-oxidizing archaeon *Nitrosopumilus* to a new phylum of *Archaea*, the *Thaumarchaeota*.

While it was believed that the Black Death was caused by a massive outbreak of bubonic plague, a typically fatal disease caused by the bacterium *Yersinia pestis* (► Section 32.7), scientists could not be positive until they recovered and sequenced DNA samples from the teeth and bones of corpses of people known to have died from the Black Death. By comparisons of this ancient DNA with the genome of *Y. pestis*, the mystery behind this devastating medieval disease was unraveled: The Black Death was indeed bubonic plague.

Microbial genomics has also been used to identify new microbial phyla. For example, until recently, only three phyla of *Archaea* were known—*Euryarchaeota*, *Crenarchaeota*, and *Nanoarchaeota* (Chapter 17). Because every cultured species was isolated from an extreme environment, many microbiologists concluded that *Archaea* were mainly extremophiles and that they did not inhabit oceans, lakes, and soil in significant numbers. However, based on environmental 16S rRNA gene sequencing, *Archaea* only marginally affiliated with *Crenarchaeota* were detected in marine and freshwater samples. Who were these organisms, and how were they making a living? Subsequently, *Nitrosopumilus*, the first ammonia-oxidizing (nitrifying) archaeon known, was isolated (Figure 10.3b; ► Section 14.9). Using the powerful analytical tools of genomics, the genomes of two distinct ammonia-oxidizing *Archaea* were compared with those of all other *Archaea*. This genomic analysis clearly showed that these ammonia-oxidizing *Archaea* belonged in a new phylum, now called the *Thaumarchaeota* (► Section 17.5).

The above is just a taste of how genomics has impacted microbiology. Other relevant examples will appear regularly as you make your way through this text. The major message here is twofold: (1) We are clearly living in the era of microbial genomics, and (2) the genomics revolution has spawned a wealth of powerful tools to attack old problems in new ways. Indeed, in the past 40 years or so, microbiology as a science has leapt forward farther and faster than at any time in its history.

Check Your Understanding

- How many protein-encoding genes are in the human genome?
- List three examples of how genomics has led to major new discoveries in microbiology.

10.2 Sequencing and Annotating Genomes

In biology, the term **sequencing** refers to determining the precise order of subunits in a macromolecule. In the case of DNA (or RNA), the sequence is the *order* in which the nucleotides are aligned. DNA sequencing today forms the heart of the omics revolution and its technology is advancing so quickly that new methods appear every year. Yet despite the technological breakthroughs that have catapulted us into the omics age, some of the earliest sequencing methodologies—born of simple yet brilliant basic science—form the foundation of the latest methods today (see next subsection).

After sequencing and assembly of the gene fragments, the next step is *genome annotation*, the conversion of raw sequence data into a list of the genes and other functional sequences present in the genome. The term **bioinformatics** refers to the use of computers to store and analyze the sequences and structures of nucleic acids and proteins. Improved sequencing methods are now generating data almost faster than it can be properly analyzed. Thus, although automated annotation software exists and powerful new versions are being developed at a rapid pace, annotation remains the major “bottleneck” in genomics. Here we focus on the process of genome sequencing, assembly, and annotation.

DNA Sequencing

The first widely used method for sequencing DNA was the *dideoxy method* developed by the British scientist Fred Sanger, who won a Nobel Prize (his second) for this accomplishment. In the Sanger procedure the sequence is determined by making a copy of the original single-stranded DNA in a process similar to the polymerase chain reaction (PCR, ► Section 12.1). The secret behind the Sanger method was the addition of a mixture of normal deoxyribonucleotides (dNTPs) and small amounts of the corresponding *dideoxynucleotides* (ddNTPs), one for each of the four bases—adenine, guanine, cytosine, and thymine—to the mixture used to make the DNA copy (Figure 10.4a). The dideoxy analog is a specific *chain-terminator*; because it lacks a 3′-hydroxyl, the analog prevents further elongation of the chain after its insertion. Because ddNTPs insert randomly, DNA chains of varying length are produced in the synthesis reaction (Figure 10.4a). Sanger sequencing originally used radioactive labels, but automated systems were quickly developed that used a separate fluorescent label for each different ddNTP and detected the DNA products (separated by passing through a sizing column) with a laser (Figure 10.4a).

Because the original Sanger method was dependent on primers binding to a known sequence and was limited to around 800 nucleotides per reaction, entire chromosomes or large DNA molecules could not be sequenced in a single reaction. Instead large DNA molecules had to be cut into smaller fragments and cloned into vectors for sequencing. This led to the development of new sequencing technologies, which appear now with such regularity that the term “next-generation sequencing” is commonly used to describe the

Mastering
Microbiology
Art Activity:
Figure 10.4a
DNA
sequencing

Figure 10.4 DNA sequencing. (a) Sanger sequencing. When a polymerase incorporates a ddNTP during synthesis, the chain of DNA is terminated. The identity of the terminal ddNTP can be determined by capillary electrophoresis and fluorescence detection. (b) Pyrosequencing. Whenever a new dNTP is inserted into the growing strand of DNA (red arrows), pyrophosphate (PP_i) is released and is used to make ATP from AMP by the enzyme sulfurylase. The ATP is consumed by the enzyme luciferase, which releases light. Unused dNTPs are degraded by the enzyme apyrase (gray arrow).

latest and greatest in nucleic acid sequencing. For example, *pyrosequencing*, a *second-generation sequencing method* still widely used today, is based on the Sanger method and employs the light-emitting enzyme luciferase to detect incorporation of dNTPs by emitting a pulse of light (Figure 10.4b). It should be noted that despite the advent of new sequencing technologies, the Sanger method is still routinely used to sequence plasmid constructs and PCR products. **Table 10.2** summarizes modern sequencing methods and illustrates how the cost of sequencing 1 megabase (Mbp, million base pairs) of DNA dropped over 100,000-fold in 15 years.

Genome Assembly and Annotation

Regardless of which sequencing system is used—even hand-held systems are available today (see Explore the Microbial World, DNA

Sequencing in the Palm of Your Hand, on page 336)—the sequences obtained must be *assembled* before they can be analyzed. Genome assembly consists of putting the fragments in the correct order to reconstruct the chromosome and eliminating any overlaps that may appear. Then, for assembled genomic sequences to be useful, they must be *annotated* in order to identify genes and other functional regions. Many of the tasks surrounding genome assembly and annotation are highly computational. For genome assembly, a computer examines many short DNA fragments that have been sequenced and deduces their order by detecting all of the instances where two fragments of DNA possess overlapping sequence (Figure 10.5). These overlaps are used to merge sequencing reads into *contigs*, or contiguous consensus sequences. Individual contigs with overlapping ends are then aligned to form scaffolds (contigs as well as gaps) that are ultimately used to generate a map representing the complete genome.

From the genome map, the annotation process can begin. Because the genomes of *Bacteria* and *Archaea* possess very few intervening sequences (introns, ◀ Section 6.6), their genomes essentially consist of a series of **open reading frames (ORFs)** separated by short regulatory regions and transcriptional terminators. A *functional ORF* is one that actually encodes a protein (◀ Section 6.9) and can be identified from a computer search of the sequence (Figure 10.6). Although any given cellular gene is always transcribed from one DNA strand, a gene can actually be located on either strand and thus computer inspection of both strands of DNA is required.

Finding and Identifying ORFs

The first step in finding an ORF is to locate *start* and *stop* codons in the sequence (◀ Section 6.9 and Table 6.4). However, in-frame start and stop codons appear randomly with reasonable frequency;

Figure 10.5 Computer assembly of DNA sequence. Most DNA sequencing methods generate vast numbers of short sequences (30 to several hundred bases) that must be assembled. The computer searches for overlaps in the short sequences and then arranges them to form contigs, or a consensus sequence.

TABLE 10.2 DNA sequencing methods		
Generation	Method	Features
First generation	Sanger dideoxy method (radioactivity or fluorescence; DNA amplification)	Read length: 700–900 bases Used for the Human Genome Project
Second generation	454 Pyrosequencing (fluorescence; DNA amplification; massively parallel) Illumina/Solexa method (fluorescence; DNA amplification; massively parallel)	Read length: 400–700 bases Used to sequence genome of James Watson (completed 2007) Read length: 50–150 bases Giant panda genome (2009; Beijing Genome Institute); Denisovan genome (2010) Read length 50–100 bases
	SOLiD method (fluorescence; DNA amplification; massively parallel) Ion torrent (electronic—pH; DNA amplification)	Read length: 200–400 bases Used to sequence genome of Intel cofounder Gordon Moore
Third generation	Pacific Biosciences SMRT (fluorescence; single molecule; zero mode waveguide)	Read length: 2500–3000 bases
	Oxford nanopore (electronic—current; single molecule; real time)	Read length: 9000 bases Portable MinION unit is approximately the size of a flash drive

thus, further clues are needed. In *Bacteria*, translation begins at start codons located immediately downstream of a ribosome-binding sequence (RBS or Shine–Dalgarno site) on the mRNA (◀ Section 6.9). Thus, locating potential ribosome-binding sequences in addition to start and stop codons helps decide both whether an ORF is functional and which start codon is actually used. In addition, an ORF is more likely to be functional if its sequence is similar to those of ORFs in the genomes of other organisms (regardless of whether they encode known proteins) or if the ORF includes a sequence known to encode a protein functional domain. This is because proteins with similar functions in different cells tend to share a common evolutionary origin and thus share sequence and

structural features (▶ Section 13.8). A computer can search for sequence similarities in major databases such as GenBank (<http://www.ncbi.nlm.nih.gov/Genbank/>) using *BLAST* (Basic Local Alignment Search Tool), an algorithm that can compare a nucleic acid or protein sequence with all other such sequences in the database.

Other issues must be considered in a genome annotation as well. For example, more than one codon exists for many of the 20 common amino acids (◀ Table 6.4), and some codons are used more frequently than others. The latter is known as **codon bias** (codon usage) and differs greatly between organisms. For example, Table 10.3 shows the different usage of the six arginine codons in *Escherichia coli* compared to their usage in humans and fruit flies. If the codon bias in a given ORF differs greatly from the consensus for the organism containing it, that ORF may be non-functional or may be functional but obtained by horizontal gene transfer (▶ Section 13.9).

Figure 10.6 Computer identification of possible ORFs. The computer scans the DNA sequence looking first for start and stop codons. It then counts the number of codons in each uninterrupted reading frame and rejects those that are too short. The probability of a genuine ORF is made stronger if a likely ribosomal binding site (RBS) is found the correct distance in front of the reading frame. Codon bias calculations are used to test whether an ORF complies with the codon usage of the organism being examined.

Genomic Analyses: The Final Tally

No genome sequence project ends with 100% of the genome identified. In fact, this is one of the most exciting and challenging findings of genomic analyses: Many genes in microbes almost certainly encode proteins whose function(s) remain unknown. Although there are differences among organisms, in most genomes the percentage of genes whose role can be clearly identified is approximately 70% of the total number of ORFs detected. Uncharacterized (or unknown) ORFs are said to encode *hypothetical proteins*, proteins that probably exist although their function is unknown. These ORFs have uninterrupted reading frames of reasonable length and the necessary start and stop codons and ribosome-binding site (Figure 10.6); however, the proteins they encode lack sufficient amino acid sequence homology with any known protein to be unambiguously identified. Some gene annotations can only assign a gene to a protein family or to a general function (such as “transport protein”) without being more specific. Many of the unidentified genes in *E. coli* are thought to encode proteins that play a role in some unidentified regulatory process or are proteins

TABLE 10.3 Examples of codon bias

Arginine codon ^a	Usage of each arginine codon (%)		
	<i>Escherichia coli</i>	Fruit fly	Human
AGA	1	10	22
AGG	1	6	23
CGA	4	8	10
CGC	39	49	22
CGG	4	9	14
CGU	49	18	9

^aArginine has six codons; see Table 6.4.

required only for special nutritional or environmental conditions. A few may also function as “backups” of key enzymes. Later in this chapter we will discuss methods, which are only possible because of the omics revolution, to help identify the function of these hypotheticals (Sections 10.5 and 10.7).

In addition to protein-encoding genes, some genes encode RNA molecules that are not translated. Such genes therefore lack start codons and may well have multiple stop codons within the gene. Some noncoding RNAs, such as tRNAs and rRNAs, are easy to detect because they are well characterized and are highly conserved. However, many noncoding regulatory RNA molecules (◀ Section 7.12) are conserved only in their three-dimensional structure, with little sequence homology. Thus transcriptomics, specifically RNA-Seq (Section 10.8), has become instrumental in identifying these noncoding genes.

With this general background in nucleic acid sequencing and the coding features of genomes, we move on to compare the nature of genomes in various microbial groups. We begin with the *Bacteria* and *Archaea* where thousands of genome sequences are available for comparative analyses.

- What key molecules are essential for Sanger sequencing?
- What is an open reading frame (ORF)? What is a hypothetical protein?
- What is the major problem in identifying genes encoding non-translated RNA?

10.3 Genome Size and Gene Content in *Bacteria* and *Archaea*

Once a genome has been assembled, *comparative genomics* using databases such as MicrobesOnline (<http://www.microbesonline.org>)—which contains nearly 4000 microbial genome sequences—can be used to probe its biological secrets. By using comparative genomics, it has been determined that genomes of *Bacteria* and *Archaea* show a strong correlation between genome size and open reading frame (ORF) content (Figure 10.7a). Regardless of the organism, each megabase pair of DNA in a prokaryotic cell encodes about 1000 ORFs, and as the size of these genomes increases, the gene number also increases proportionally. This contrasts markedly with the genomes of eukaryotes, in which noncoding DNA (introns, ▶ Section 6.6) may constitute a large fraction of the genome, especially in organisms with large genomes (Figure 10.2).

While the sizes of bacterial genomes vary 100-fold, from the insect symbiont *Tremblaya princeps* with 121 protein-encoding genes to the soil-dwelling *Minicystis rosea* with over 14,000 genes, archaeal genomes only vary in size 10-fold (Figure 10.7b). This archaeal range encompasses the ectosymbiont *Nanoarchaeum equitans* with 552 protein-encoding genes to the methanogen *Methanosarcina acetivorans* with 4252 genes (Figure 10.2 and Table 10.1). Whereas about 1300 genes have been the predicted minimum for the number necessary for a cell to have a *free-living* existence, recent environmental

(b)

Figure 10.7 Bacterial and archaeal genome size and content. (a) Correlation between genome size and ORF content in prokaryotic cells. Analyses of 115 completed genomes from species of both *Bacteria* and *Archaea*. Data from Konstantinidis, K.T., and Tiedje, J.M. 2004. *Proc. Natl. Acad. Sci. (USA)* 101: 3160. (b) Distribution of genome sizes among a representative sample of *Archaea* (blue) and *Bacteria* (green). Genomes were chosen based on even distribution across the two phylogenetic domains. Shared frequency of occurrence data points are represented in red. Data adapted from Kellner, S., Spang, A., Offre, P., Szöllosi, G.J., Petitjean, C., and Williams, T.A. 2018. *Emerging Top. Life Sci.* doi: 10.1042/ETLS20180021.

metagenomic (◀ Figure 1.1 and Section 10.7) datasets have called this earlier estimate into question; individual genomes have been assembled from various environments that contain only 600 to 800 genes (◀ Chapter 1 Explore the Microbial World, “Tiny Cells”). Representative organisms for these genomes are not yet in culture to determine if they are free-living bacteria, but if they are, the genetic requirements for a free-living cell are far lower than originally suspected.

Small Genomes

The smallest cellular genomes belong to bacteria that are parasitic or endosymbiotic (cells that live inside other cells), with the insect symbionts *Tremblaya* (in mealybugs) and *Hodgkinia* (in cicadas) possessing some of the smallest genomes (around 140 kbp, Table 10.1 and Figure 10.8). The absolute smallest genome discovered thus far is that of *Nasua deltocephalica*, a sap-feeding insect symbiont whose genome is only 112 kbp. Because of their reduced genome size, such symbionts are totally dependent on their insect host cells for survival and nutrients. In turn, the symbionts provide the insect with essential amino acids and other nutrients that the insect cannot synthesize.

1. <i>Mycoplasma genitalium</i> (Mollicutes) 580.1 kbp GC: 31.7%	4. <i>Carsonella</i> (Gammaproteobacteria) 159.6 kbp GC: 16.6%
2. <i>Tremblaya</i> (Betaproteobacteria) 138.9 kbp GC: 58.8%	5. <i>Hodgkinia</i> (Alphaproteobacteria) 143.7 kbp GC: 58.4%
3. <i>Zinderia</i> (Betaproteobacteria) 208.5 kbp GC: 13.5%	6. <i>Sulcia</i> (Bacteroidetes) 245.5 kbp GC: 22.4%

Figure 10.8 Symbiont genomes. Five insect symbiont genomes are shown drawn to scale inside the circle representing the genome of a *Mycoplasma*. Blue: genes encoding genetic information processing; red: genes encoding amino acid and vitamin biosyntheses; yellow: rRNA genes; white: other genes; gaps indicate noncoding DNA. Kbp, kilobase pairs. GC indicates percentage of nucleotides that are guanine or cytosine.

With genomes of around 500 kbp, *Mycoplasma* (Bacteria) and *Nanoarchaeum equitans* (Archaea) have the smallest genomes among parasitic prokaryotic cells (Table 10.1). *N. equitans* is a hyperthermophile and a parasite of another hyperthermophile, the archaeon *Ignicoccus* (▶ Section 17.11). *N. equitans* lacks virtually all genes that encode metabolic proteins and presumably depends on its host for most catabolic as well as anabolic functions. While some pathogens such as *Mycobacterium tuberculosis* have quite large genomes (4.4 Mbp), the genomes of most human pathogens, such as *Mycoplasma*, *Chlamydia*, and *Rickettsia*, are smaller than the largest known viral genome, that of *Pandoravirus* (2.5 Mbp, ▶ Section 11.1).

Using *Mycoplasma*, which has around 525 genes, as a starting point, it has been estimated that around 250–300 genes are the minimum number possible for a viable cell. These estimates rely partly on comparisons with other small genomes. In addition, systematic mutagenesis has been performed to identify essential genes. For example, experiments with *Escherichia coli* and *Bacillus subtilis*, both of which have about 4000 genes, indicate that approximately 300–400 genes are essential depending on the growth conditions. In fact, synthetic biologists have been able to create a minimal *Mycoplasma* bacterium with 473 genes (▶ Section 12.12). While this is only 52 genes fewer than that of the *Mycoplasma genitalium* genome (Table 10.1), the designer microbe has a doubling time of 3 hours versus the weeks of the original *M. genitalium*. Thus the trimmed-down genome benefits the synthetic bacterium in the laboratory.

Large Genomes

Some Bacteria have genomes that are as large as those of some eukaryotic microbes. In fact, because eukaryotes tend to have significant amounts of noncoding DNA and bacteria do not (Section 10.4), some bacterial genomes actually have more genes than microbial eukaryotes, despite having less DNA. For example, the genome of *Bradyrhizobium japonicum*, a bacterium that forms nitrogen-fixing root nodules on leguminous plants such as soybeans (▶ Section 23.4), has 9.1 Mbp of DNA and 8300 ORFs, whereas the genome of the baker's yeast *Saccharomyces cerevisiae*, a eukaryote, has 12.1 Mbp of DNA and only 5400 ORFs (see Tables 10.1 and 10.5).

The second largest bacterial genome known is that of *Sorangium cellulosum*, a species of the gliding myxobacteria (▶ Section 15.16; little has been reported on the larger *M. rosea* genome, Table 10.1). With just under 14.8 Mbp on a single circular chromosome, *S. cellulosum* has more DNA than several eukaryotes including yeast and the pathogenic protozoans *Cryptosporidium* and *Giardia* (see Table 10.5). The *S. cellulosum* genome is composed of roughly 10.5% noncoding DNA and 11,559 protein-encoding genes, making it over three times larger than the genome of *E. coli*. Interestingly, the *S. cellulosum* genome encodes 508 kinases (enzymes that phosphorylate other proteins to regulate their activity), which is over three times that of any other genome including those of eukaryotes. This suggests that the lifestyle of *S. cellulosum* is highly diverse and that its ecological success requires extensive regulation. In contrast to Bacteria, the largest genomes found in species of Archaea thus far are only about 5 Mbp (Table 10.1).

DNA Sequencing in the Palm of Your Hand

DNA sequencing technologies are revolutionizing microbiology at a remarkable pace. Innovations in next-generation sequencing have even tackled the difficult issues of cost and portability. The world's first mobile nucleic acid sequencer—the MinION—is a palm-sized device that possesses 2000 tiny pore-containing proteins called nanopores. As single strands of nucleic acid travel through the nanopores, individual nucleotides are identified in real time based on changes in electrical current (**Figure 1**). These current changes are relayed to a computer through a USB connection, which also powers the MinION. This miniature but mighty machine can display nucleic acid sequences from critical field samples in real time on a computer screen.

Besides its portability, the methodology behind the nanopore technology yields extremely long sequencing reads compared to other next-generation sequencing methods (Table 10.2). This feature is being exploited to quickly sequence complete microbial genomes as well as to “close” those genomes that have been difficult because of their troublesome nucleotide repeats. The identification of nucleotides based on changes in electrical current as they travel through a nanopore also allows for modified nucleotides,

such as those with additional methyl groups, to be detected. This feature is of interest to microbiologists who study gene regulation, as the methylation state of gene promoters can control gene expression; such is the case with genes that encode mobile gene elements such as transposases (◀ Section 9.11) that play critical roles in horizontal gene transfer and genome evolution (Chapter 13).

The utility of the MinION's portability was clearly on display during the 2014–2015 Ebola virus hemorrhagic fever outbreak in West Africa. Scientists traveled to Guinea with three MinIONs in their luggage, a feat in itself as most DNA sequencers are too large and delicate to travel in baggage. Once in Guinea, scientists were able to survey the spread of different Ebola virus strains by analyzing unique nucleotide sequences present in each strain's genome. In as little as 48 hours after sample collection, Ebola virus genomes from 14 patients were determined using MinION sequencing.¹

Figure 2 shows a researcher loading a patient's sample onto a MinION set up in a mobile field laboratory (inset).

Because the Ebola genome mutates rapidly, the astonishing turnaround time provided by the MinION allowed epidemiologists to track geographical movements of different strains of the virus. This real-time analysis indicated that two major viral strains were the cause of Ebola persistence and that cross-border transmission between Sierra Leone and Guinea severely prolonged the outbreak.² Traditional sequencing methods would not have supported such surveillance, as it requires weeks to obtain results after shipment of samples to remote laboratories.

Figure 2 Use of the MinION in the field during the 2015 Ebola outbreak in West Africa. Credits: © EMLab/Tommy Trenchard 2016.

While biologists have envisioned numerous uses for the MinION, it has already been tested by NASA on the International Space Station. During this test, the MinION's ability to sequence the genomes of *Escherichia coli*, bacteriophage lambda, and mouse DNA was not hampered by the microgravity of outer space.³ In addition, the MinION has proven durable and dependable even in such remote and extreme locations as Antarctica,⁴ opening up the possibility that the large sequencing requirements of modern-day microbial ecology may be fulfilled, at least in part, right in the field at the time of sample collection. Moreover, developers are currently attempting to modify the portable sequencer to operate from a smartphone instead of a computer. And, because of its size, relatively low cost, and ease of use, the next frontier for the MinION will undoubtedly be the classroom.

Figure 1 Nanopore-MinION sequencing. A DNA double helix is converted to a single strand for passage through a membrane-bound pore. As the DNA transits the nanopore, it causes changes in electric current that are base-specific and thus reveal the DNA sequence.

Gene Content of Bacterial Genomes

The complement of genes in a particular organism reveals its capabilities. Conversely, genomes are molded by adaptation to particular lifestyles. Comparative analyses are useful when searching for genes that encode enzymes that probably exist because of the lifestyle of an organism, and in some cases these searches yield big surprises. For example, *Vampirovibrio chlorellavorus* is a predatory bacterium that attacks its host, the green alga *Chlorella*, by surface attachment and ultimate ingestion of its cellular contents (thus the terms “vâmpîr” from Hungarian, meaning “blood sucker,” and “vorus” from Latin, meaning “to devour,” in the organism’s name). Isolates of *V. chlorellavorus* existed only as 36-year-old freeze-dried samples that had not been successfully revived. However, by using advanced sequencing techniques, the genome of *V. chlorellavorus* was recovered, and surprisingly, genomic analyses indicated that *V. chlorellavorus* falls within the phylum *Cyanobacteria* (► Section 15.3) even though it lacks genes for photosynthesis.

Figure 10.9, reprinted from a scientific journal, is included here to give you an idea of why a microbe’s genome should be sequenced and the amazing amount of information that can be gleaned from annotation, though the details are beyond the scope of this chapter. The figure summarizes some of the metabolic pathways and transport systems of *V. chlorellavorus* deduced from analysis of its genome. These include an electron transport chain for microaerobic growth

(◄ Section 4.16), the ability to ferment (◄ Sections 3.6 and 3.7), chemotaxis abilities (◄ Section 2.11), and the synthesis of 15 of the 20 essential amino acids (◄ Figure 6.27). Comparative genomics also indicated that *V. chlorellavorus* used a conjugative type IV secretion system (◄ Section 6.13) to attack its prey, the first discovery of this strategy in a predatory bacterium.

A functional analysis of genes and their activities in several bacteria is given in Table 10.4. Thus far, a distinct pattern of gene distribution in *Bacteria* has emerged. Metabolic genes are typically the most abundant class in bacterial genomes, although genes for protein synthesis overtake metabolic genes on a percentage basis as genome size decreases (Table 10.4 and Figure 10.10). Although many genes can be dispensed with, genes that encode the protein-synthesizing apparatus cannot. Thus, the smaller the genome, the greater the percentage of genes that encode translational processes. Conversely, the larger the genome, the more genes there are for transcriptional regulation and signal transduction (Chapter 7).

Analyses of gene categories have also been done for several *Archaea*. On average, *Archaea* devote a higher percentage of their genomes to energy and coenzyme production than do *Bacteria* (this result is undoubtedly skewed a bit due to the large number of novel coenzymes produced by methanogenic *Archaea*, ► Section 14.15 and Figure 14.36). On the other hand, *Archaea* appear to contain fewer genes for carbohydrate metabolism and membrane functions

Figure 10.9 Functional and metabolic predictions for *Vampirovibrio chlorellavorus* based on genomic annotation. Although the details are beyond our discussion, the figure illustrates the power of genomic sequencing and annotation on piecing together the physiology of an organism. Within the cytoplasmic membrane, the following systems are highlighted: secretion (green),

chemotaxis and movement (blue), electron transport (red), ATP-binding cassette transporters (yellow), and permeases/pumps/transporters (orange). Black ovals indicate substrates that enter the glycolysis pathway, while fermentation end products are indicated as black rectangles. Colors of internal compounds correspond to the following: green (amino acids), red

(cofactors and vitamins), purple (nucleotides), and orange (non-mevalonate pathway products). Note that genes for synthesis of serine (highlighted in blue) are not present, so presumably it is transported into the cell. Adapted from Soo, R.M., et al. 2015. *Peer J.* 3: e968.

TABLE 10.4 Gene function in some genomes of *Bacteria*

Functional categories	Percentage of genes

^aChromosome size, in megabase pairs. Each organism listed contains only a single circular chromosome.

(such as transport and membrane biosynthesis) than do *Bacteria*. However, this conclusion may also be skewed a bit because the corresponding pathways have been less studied in *Archaea* than in *Bacteria* and many of the relevant archaeal genes remain unidentified.

We now transition to look at the genomes of eukaryotes and their major organelles, structures whose evolutionary roots lie in the *Bacteria*.

Check Your Understanding

- What lifestyle is typical of *Bacteria* and *Archaea* that contain fewer than 500 protein-encoding genes?
- Which is likely to have more genes, a species of *Bacteria* with 8 Mbp of DNA or a eukaryote with 10 Mbp? Explain.
- In prokaryotic cells with the largest genomes, which gene category contains the largest percentage of genes?

Figure 10.10 Functional category of genes as a percentage of the genome. The percentage of genes encoding products for translation or DNA replication is greater in organisms with small genomes, whereas the percentage of transcriptional regulatory genes is greater in organisms with large genomes.

10.4 Organelle and Eukaryotic Microbial Genomes

Mitochondria and chloroplasts are eukaryotic cell organelles derived from endosymbiotic bacteria (◀ Section 2.14 and ▶ Section 18.1) and thus share many fundamental traits with *Bacteria* to which they are phylogenetically related. The genomes of both organelles encode the machinery necessary for protein synthesis including ribosomes, transfer RNAs, and the other components necessary to drive translation. The genomes of several microbial eukaryotes have also been sequenced (Table 10.5), and their size varies widely (Figure 10.2). Certain single-celled protozoans, including the free-living ciliate *Paramecium* (40,000 genes) and the pathogen *Trichomonas* (60,000 genes), have significantly more genes than do humans (Table 10.5). In this section we focus on organellar genomes and the genomes of a few select microbial eukaryotes.

The Chloroplast Genome

Green plant and algae cells contain chloroplasts, the organelles that perform photosynthesis (▶ Section 14.3 and Figure 14.9). Each chloroplast contains several identical copies of the genome. Until recently, it was accepted that all chloroplast genomes were circular DNA molecules. However, with the power of next-generation sequencing, linear and single-stranded plasmid-like chloroplast genomes have also been detected. In fact, most of the chloroplast genomes in corn (maize) are linear in structure. Based on the over 800 chloroplast genomes in the databases, the typical chloroplast genome is about 100–200 kbp and contains two inverted repeats of 6–76 kbp that each encode copies of the three rRNA genes (Figure 10.11). As might be expected, many

Figure 10.11 Map of a typical chloroplast genome. The inverted repeats each contain a copy of the three genes for rRNA (5S, 16S, and 23S). The large subunit of RuBisCO is encoded by *rbcL* and the chloroplast RNA polymerase by *rpo* genes. Inset: Photo of four cells of the green alga *Makinoella* with chloroplasts clearly visible.

chloroplast genes encode proteins for photosynthetic reactions and autotrophy. For example, the enzyme RuBisCO, which is composed of a small and large subunit, catalyzes the first step in CO₂ fixation in the Calvin cycle (◀ Section 3.12 and ▶ Section 14.2). The *rbcl* gene encoding the large subunit of RuBisCO is present on the chloroplast genome (Figure 10.11), whereas the gene for the small subunit, *rbcS*, resides in the plant cell nucleus and its protein product must be imported from the cytoplasm into the chloroplast after synthesis.

The chloroplast genome also encodes tRNAs used in translation, several proteins used in transcription and translation, and some other proteins. Not all chloroplast proteins are encoded by the chloroplast genome; some are nuclear encoded. These are likely genes that migrated to the nucleus as the chloroplast evolved from an endosymbiotic cell into a photosynthetic organelle. Introns, the hallmark of genes in eukaryotes, are common in chloroplast genes and are primarily of the self-splicing type (◀ Section 6.6).

Mitochondrial Genomes and Proteomes

Mitochondria are the eukaryotic cell’s respiratory organelles and are present in all but a few eukaryotes (◀ Section 2.14 and ▶ Section 18.1). Mitochondrial genomes primarily encode proteins for oxidative phosphorylation and, like chloroplast genomes, also encode proteins, rRNAs, and tRNAs for protein synthesis. However, most mitochondrial genomes encode far fewer proteins than those of chloroplasts. The largest mitochondrial genome known has

only 62 protein-encoding genes, but others contain as few as three. The mitochondria of almost all mammals, including humans, encode only 13 proteins in addition to 22 tRNAs and 2 rRNAs. Figure 10.12a shows a map of the 16,569-bp human mitochondrial genome. While human mitochondrial genomes are circular, diverse arrangements exist in other organisms. For example, some mitochondrial genomes are linear, including those of certain algae, protozoans, and fungi. Finally, the mitochondria of many fungi and flowering plants contain, in addition to the mitochondrial genome, small circular or linear plasmids (◀ Section 6.2).

Mitochondria require many more proteins than their genome encodes (in particular, proteins needed for translation), and thus many mitochondrial proteins are encoded by genes in the nucleus. The yeast mitochondrion contains as many as 800 different proteins in its proteome (all the proteins encoded by a genome; Section 10.9). However, only eight (~1%) of them are encoded by the yeast mitochondrial genome, the remaining proteins being encoded by nuclear genes (Figure 10.12b). The nuclear-encoded proteins required for translation and energy generation in mitochondria are more closely related to their counterparts in *Bacteria* than to those in the eukaryotic cytoplasm, consistent with both the evolutionary history of the mitochondrion (▶ Section 13.4) and with a scenario—like that seen in the chloroplast—of genes having migrated from the original endosymbiont to the host cell nucleus.

Figure 10.12 Map of the human mitochondrial genome and the mitochondrial proteome. (a) The genome encodes rRNAs, 22 tRNAs, and several proteins. Arrows show direction of transcription for genes of a given color, and the three-letter amino acid designations for tRNA genes are also shown. The 13 protein-encoding genes are in green. *Cytb*, cytochrome *b*; ND1–6, components of the NADH dehydrogenase complex; COI–III, subunits of the cytochrome oxidase complex; ATPase 6 and 8, polypeptides of the mitochondrial ATPase complex. The two promoters are in the region called the D loop, which is also involved in DNA replication. Inset: Transmission electron micrograph of a mitochondrion (credit, D.W. Fawcett). (b) Mitochondrial proteomes. The numbers in each colored bar are the number of proteins encoded on the mitochondria of some model eukaryotes.

Genomes and Introns in Some Microbial Eukaryotes

Apart from the human pathogenic protozoan *Trichomonas*, which contains almost three times more genes than human cells, parasitic eukaryotic microorganisms typically have relatively small genomes of 10–40 Mbp containing between 4000 and 11,000 genes. For example, *Trypanosoma brucei*, the agent of African sleeping sickness (► Section 34.6), has 11 chromosomes, 35 Mbp of DNA, and almost 11,000 genes. The four species of *Plasmodium* that infect humans (causing malaria, ► Section 34.5) have genomes ranging from 23 to 27 Mbp arranged in 14 chromosomes containing a total of about 5500 genes.

As in *Bacteria*, the smallest eukaryotic genome belongs to an endosymbiont. Known as a *nucleomorph*, it is the degenerate remains of a eukaryotic endosymbiont of a certain green alga that has acquired the ability to photosynthesize by secondary endosymbiosis (► Section 18.1). Nucleomorph genomes range from about 0.37 to 0.85 Mbp. The smallest genome in a parasitic eukaryote belongs to *Encephalitozoon intestinalis*, an intracellular pathogen of humans and other animals. *E. intestinalis* even lacks mitochondria, and although its haploid genome contains 11 chromosomes, the genome size is only 2.3 Mbp with approximately 1800 genes (Table 10.5); this is smaller than many bacterial genomes (Table 10.1).

The baker's yeast *Saccharomyces cerevisiae* is widely used as a model eukaryote and its genome contains 16 chromosomes (13.4 Mbp of DNA). Yeast has approximately 6000 ORFs, which is fewer than that of some genomes of *Bacteria* (Tables 10.1 and 10.5). How many of these yeast genes are actually essential? This question has been addressed by systematically inactivating each gene in turn

with *knockout mutations* (mutations that completely inactivate genes, ► Section 12.4). Knockout mutations cannot normally be obtained in essential genes in a haploid organism. However, yeast can be grown in both diploid and haploid states (► Section 18.10). By generating knockout mutations in diploid cells and then investigating whether they can also exist in haploid cells, it is possible to determine whether a particular gene is essential for cell viability. Using knockout mutations, it has been shown that around 900 yeast ORFs (17% of its genome) are absolutely essential. Note that this number of essential genes is much greater than the approximately 300 genes estimated to be the minimal number required in a bacterial cell (Section 10.3).

Being a eukaryote, the yeast genome contains introns (◄ Section 6.6). However, the total number of introns in the protein-encoding genes of yeast is a mere 225. Most yeast genes that contain introns have only a single small intron near the 5' end of the gene. This situation differs greatly from that seen in more complex eukaryotes (Figure 10.13). For example, in the worm *Caenorhabditis elegans*, the average gene has five introns, and in the fruit fly *Drosophila*, the average gene has four. Introns are also common in the genes of plants, averaging around four per gene. The model flowering plant *Arabidopsis* averages five introns per gene, and over 75% of *Arabidopsis* genes have introns. In humans almost all protein-encoding genes have introns, and it is common for a single gene to have 10 or more. Moreover, introns in human genes are typically much longer than exons, the DNA that actually encodes proteins. Indeed, exons make up only about 1% of the human genome, whereas introns account for 24%. The remaining

Figure 10.13 Intron frequency in the genes of different eukaryotes. The average number of introns per gene is shown for a range of eukaryotic organisms; microbial species tend to have fewer introns per gene, whereas plants and animals have the most.

DNA is made up of repetitive sequences, noncoding RNA, and regulatory regions.

We will discuss how comparative genomics can be used to determine evolutionary relationships and how genomes evolve in Chapter 13. For now, we turn our focus to how various omic approaches can be used to determine the function of each gene product. The dynamic nature of microbes and how they interact with their environment can be characterized through the use of functional omics.

Check Your Understanding

- What is unusual about the genes that encode mitochondrial proteins?
- What do chloroplast genomes typically encode?
- What is unusual about the genome of the eukaryote *Encephalitozoon*?

II • Functional Omics

Knowing an organism’s genome sequence may not reveal what all the genes encode and when and why they are transcribed and translated. These topics require functional analyses of molecular events downstream of the genome itself.

Despite the major effort required to generate an annotated genome sequence, the net result is simply a “list of parts.” To understand how a cell *functions*, we need to know more than which genes are present. We must also understand (1) gene expression, (2) the function of gene products, (3) the activity of the proteins made, and (4) the metabolites produced during growth.

In analogy to the term “genome,” the entire complement of RNA, proteins, or metabolites produced under a given set of conditions is called the *transcriptome*, *proteome*, and *metabolome*, respectively. The suffix “omic” denotes their corresponding areas of study. Table 10.6 summarizes some of the “omics” terminology used in microbiology today.

10.5 Functional Genomics

As previously discussed (Section 10.2), genome sequencing, assembly, and annotation yields an abundance of information. However, the roles of many open reading frames (ORFs) remain unknown after annotation and are thus classified as encoding “hypothetical proteins.” The percentage of hypotheticals in a given microbial genome averages 30% of the total annotated ORFs. This value even holds true for the minimal *Mycoplasma* genome created by synthetic biologists, which possesses a trim 473 genes (► Section 12.12). In fact, the function of less than 1% of the approximately 120 million protein sequences that exist in public databases is known! Thus, obtaining a genome sequence is only the *beginning* of teasing apart how a microbe functions and survives in its environment.

In this unit of the chapter we discuss how to gain insight into gene function through the analysis of RNA, protein, and metabolites, and we begin with how comparative genomics, genetic tools, and next-generation sequencing can be used to determine gene function.

Functional Genomics and Heterologous Expression

How do microbes get selected for genome sequencing? This selection is usually a result of an interesting phenotypic trait displayed by the microbe. Such was the case with the multi-antibiotic-resistant,

TABLE 10.6 Some omics terminology	
DNA	Genome the total complement of genetic information of a cell or a virus Metagenome the total genetic complement of all the cells present in a particular environment Epigenome the total possible epigenetic changes Methylome the total methylated sites on the DNA (whether epigenetic or not) Mobilome the total set of mobile genetic elements in a cell Resistome the total set of antibiotic resistance genes in a cell
RNA	Transcriptome the total RNA produced in an organism under a specific set of conditions Exome the part of the RNA pool encoded by exons that remains after introns are removed
Protein	Proteome the total set of proteins encoded by a genome; sometimes also used in place of <i>translatome</i> Translatome the total set of proteins present under specified conditions Interactome the total set of interactions between proteins (or other macromolecules) Secretome the total set of proteins secreted by a cell Kinome the total set of protein kinases encoded by a genome
Metabolites	Metabolome the total complement of small molecules and metabolic intermediates Glycome the total complement of sugars and other carbohydrates
Organisms	Microbiome the total complement of microorganisms in an environment (including those associated with a higher organism) Virome the total complement of viruses in an environment Mycobiome the total complement of fungi in a natural environment

gram-positive bacterium *Paenibacillus* species strain LC231 (Figure 10.14). While *Bacteria* displaying resistance to multiple drugs is not unique (► Section 28.7), strain LC231 was cultured from an underground cave ecosystem that has been isolated from the surface for over 4 million years (Figure 10.14a). With no exposure to current pathogens (where it could have picked up genes by horizontal transfer, Chapter 9) or to antibiotics used in clinical or veterinary medicine, this bacterium displayed resistance—surprisingly—to at least 14 different classes of antibiotics! How did such resistance come about?

In an effort to understand the gene products or *resistome* (Table 10.6) responsible for the multidrug resistance of strain LC231, bioinformatics revealed ten ORFs known to encode resistance to seven different types of antibiotics (Figure 10.14b). This comparative genome analysis was facilitated by an online program called *Resistance Gene Identifier*, which allows for genome sequences to be searched against

a database of known antibiotic resistance genes from other bacteria. However, the mechanism by which LC231 was resistant to seven *other* antibiotic types was not evident from comparative genomics. To attack this question, microbiologists used a common functional genomics approach that employs the model bacterium *Escherichia coli*. This approach is based on *heterologous expression*, which is the process of expressing a gene from one organism in a different, host organism (Chapter 12). To heterologously express LC231 genes in *E. coli*, the LC231 genome was fragmented and inserted into plasmids. The resulting plasmids were transformed into *E. coli* to create a clone library of transformants, with each transformant containing a plasmid with a different piece of the LC231 genome (Figure 10.14a and Chapter 12). *E. coli* colonies that resulted from this clone library were then screened and selected for resistance to the antibiotics of interest. To determine the identity of the LC231 genome fragment responsible for conferring antibiotic resistance to

Figure 10.14 Functional genomics and discovery of new antibiotic resistance genes. (a) Heterologous expression of *Paenibacillus* strain LC231 DNA and selection of antibiotic-resistant transformants for sequence analysis. DNA from *Paenibacillus* strain LC231, isolated from Lechuguilla Cave, Carlsbad Caverns, New Mexico, USA (inset photo of *Paenibacillus* colonies courtesy of L. Ejim, C. Groves, and G. Wright),

is extracted and inserted into plasmids for expression in *Escherichia coli*. Plasmid DNA from antibiotic-resistant *E. coli* colonies is sequenced and analyzed for the presence of new genes conferring antibiotic resistance (AB^R). (b) Discovery of genes conferring resistance to 14 different types of antibiotics in *Paenibacillus* strain LC231. Gene names are listed under the type of antibiotic they confer resistance to.

Genes discovered by genome database searches are in blue, while genes identified by functional genomics and heterologous expression in *E. coli* from part a are in green. Data adapted from Pawlowski, A.C., Wenliang, W., Koteva, K., Barton, H.A., McArthur, A.G., and Wright, G.D. 2016. *Nat. Commun.* 7: 13803.

the transformant, the corresponding plasmid DNA was isolated and sequenced (Figure 10.14a).

The functional genomic screen in *E. coli* resulted in “mining” five new antibiotic resistance genes that had not been previously discovered (Figure 10.14b). Two of these genes encode novel enzymes that modify the antibiotics bacitracin and capreomycin by an amidohydrolase (an enzyme that removes an amine group) and acetyltransferase (an enzyme that adds an acetyl group), respectively; such modifications inactivate the antibiotics. While its environmental isolation limits strain LC231 from spreading its resistome to pathogens—assuming that deep subsurface materials are not exposed to Earth’s surface from natural catastrophes or human activities—comparative genomics has shown that the genomes of at least some subsurface-dwelling bacteria contain novel antibiotic resistance determinants that represent an untouched pool of antibiotic resistance. This discovery highlights the importance not only of monitoring antibiotic use in clinical and veterinary microbiology, but also of developing mechanisms to inhibit newly discovered antibiotic-modifying enzymes. With the abundance of mobile genetic elements, or **mobilome** components (Table 10.6 and ► Section 13.9), that exist in microbial genomes in nature, given enough time, these new antibiotic resistance genes will undoubtedly be transferred to other species and could someday emerge in human pathogens.

The Utility of Comparative Genomics: Discovery of New Antiphage Systems

In Chapter 9 we discussed some barriers to horizontal gene transfer that are employed by *Bacteria* and *Archaea*. While the role of many of these microbial “immune systems” was discovered quite by accident, the omics era has allowed for similar defense systems to be identified in thousands of genomes by searching for similar gene sequences in the databases. In the process of annotating these restriction modification, phage exclusion, and CRISPR systems (◄ Section 9.12), computational biologists have noticed that many of the genes encoding these systems are clustered next to each other within the genome on what are called *chromosomal islands* (► Section 13.10). Besides containing the systems mentioned above, these chromosomal islands also contain numerous open reading frames (ORFs) of unknown function (Section 10.2).

Using comparative genomics, molecular biologists have aligned the sequences in these chromosomal islands using a process similar to that described for genome assembly and annotation in Section 10.2. This alignment resulted in the discovery of *homologs* (ORFs possessing similar sequence and evolutionary origin; ► Section 13.8) to be enriched next to genes encoding known defense systems in the genomes of many species (Figure 10.15a). Besides the similar gene sequence and length, these unknown homologs are often found surrounded by other ORFs oriented in the same direction in many genomes. Both proximity and shared direction of transcription are strong predictors of an operon and suggest that the gene products are dependent on one another. To test if these conserved ORFs did encode antiphage systems, scientists expressed the genes in model bacteria and tested the new host’s resistance to bacteriophage infection by using a range of viruses. This study resulted in the discovery of *over ten* new antiphage systems and highlights both the constant arms race between

(b)

Figure 10.15 Comparative genomics and discovery of the DISARM antiphage system. (a) Alignment of a chromosomal island region from four separate genomes containing genes encoding known antiphage systems (yellow). A region containing unannotated homologs sharing strong sequence similarity (denoted by red dashed box) with adjacent ORFs in the same orientation is selected for functional analysis in a model bacterium. (b) Expression of the DISARM (defense island system associated with restriction–modification) antiphage system in *Bacillus subtilis*. Cells expressing the DISARM system are labeled blue, while those without DNA encoding the resistance system are labeled red. The genome of the bacteriophage added to the cells contains a DNA binding site for a fluorescently tagged protein present in both cell types. As the bacteriophage genome is replicated, more fluorescent protein binds and the blue-white foci enlarge (white arrows; 60- and 80-minute time points). Over time, bacteriophage genomes are prevented from replicating in cells expressing the DISARM system (blue cells) as indicated by the relative absence of blue-white foci.

microbes and their viruses and the previously hidden antiviral capacities present in bacterial genomes.

Figure 10.15b illustrates the antiphage activity of the DISARM (defense island system associated with restriction–modification) system that was isolated from *Bacillus paralicheniformis*. Heterologous expression of this system in *Bacillus subtilis* renders the modified bacterium resistant to eight distinct tailed bacteriophages (◄ Section 5.2) because their corresponding viral DNA does not get replicated in cells expressing the DISARM system. Conversely, cells not expressing DISARM are still replicating bacteriophage DNA 80 minutes postinfection (Figure 10.15b). While the exact mechanism behind the DISARM system is still being elucidated, it does encode a methylase—an enzyme that modifies the *host’s* DNA—and hence likely functions in a way similar to other restriction modification systems by degrading the unmethylated bacteriophage DNA (◄ Section 9.12).

10.6 High-Throughput Functional Gene Analysis: Tn-Seq

Besides the heterologous expression and related systems just discussed, if genetic studies can be performed in a microbe whose genome has been sequenced, the functional role of its genes can be characterized by constructing a library of gene mutants that allow for gene analysis on an enormous scale. The most common and random way to generate these mutants is through transposon (Tn) mutagenesis (◀ Section 9.11).

Because transposons encode antibiotic resistance genes along with their insertion sequences, Tn mutants with gene interruptions can be selected using an antibiotic that allows growth of only cells containing the transposon (such cells are resistant to the antibiotic). The application of this technique was illustrated in Figure 9.35 where a gene product that plays a role in biofilm formation was identified in *Pseudomonas aeruginosa*. However, this application required the screening of *individual* transposon mutants. By contrast, the development of next-generation sequencing technology has allowed for *high-throughput* screening of mutants. To be considered high-throughput screening, automated devices are used to gather sequence data on a large set of strains or mutants in parallel. This advancement in screening capabilities combined with transposon mutagenesis has been instrumental in the development of a powerful functional genomics tool called *transposon insertion site sequencing* (Tn-Seq). The utility of Tn-Seq is based on three premises: (1) a transposable element exists that is flanked by a specific nucleotide sequence called a *restriction site* (▶ Section 12.2) that guides a nuclease enzyme to cut at a specific chromosomal sequence outside of the transposon insertion locus; (2) distinct Tn mutants can be generated that display different *fitness profiles* in a pooled culture depending on the genomic insertion, location, and growth condition screened; and (3) it is possible to determine the chromosomal location of each transposon insertion and quantify the number of each Tn mutant in a mixed pool (Figure 10.16).

If a gene product of unknown function is beneficial or essential for the survival of a cell under a specific growth condition, its corresponding Tn mutant will display *decreased* fitness and be present at low frequency in a mixed culture of competitive transposon mutants. Conversely, if *elimination* of a gene product is beneficial under certain growth conditions, the corresponding Tn mutant will display *increased* fitness and be present at a high ratio compared to less competitive Tn mutants within the pool. Mutant fitness or abundance is measured by extracting genomic DNA from the pooled culture after exposure to a certain growth condition and digestion with a restriction enzyme (Figure 10.16c; ▶ Section 12.2) that recognizes a nucleotide sequence 20 base pairs outside of the transposon. Next-generation sequencing methods are then used to add adapters, amplify, and sequence the short region of chromosomal DNA next to the Tn insertion site (Figure 10.16c), which can then be mapped back to the genome.

Tn-Seq has been used to characterize novel genes encoding competence (◀ Section 9.6) in *Streptococcus mutans*, persistence (◀ Section 8.12) in pathogenic *Escherichia coli*, antibiotic resistance in *Enterococcus*, and amino acid biosynthesis in the anaerobic sulfate-reducing bacterium *Desulfovibrio*. Figure 10.16 illustrates a Tn-Seq scheme used to characterize cellular components in *Caulobacter crescentus*, a model bacterium for studying the cell cycle (◀ Section 8.8), that lead to susceptibility to bacteriophage ϕ CbK infection. Tn-Seq studies of a pool of Tn mutants subjected to increasing concentrations of ϕ CbK resulted in the recovery of Tn mutants with insertions in genes that encode the phage receptor protein with the highest frequency (Figure 10.16c, d). This phage receptor is essential for the transport of the phage DNA into the host and ultimate infection (Figure 10.16b and ▶ Section 5.4). However, mutants with interruptions in genes that encode proteins that help phage to initially “find” and adsorb to the bacterium, such as those encoding the flagellum and pili, decreased in abundance as more phage were added to the culture (Figure 10.16c, d). Tn mutants recovered at an intermediate level in the pool possessed insertions in genes needed to replicate the ϕ CbK genome (Figure 10.16 c, d). These mutants have the same adsorption and infection rates as the wild type but are less efficient at producing new ϕ CbK.

Because of the power of Tn-Seq, scientists have modified the technique for new discoveries. Current fitness studies can miss single-cell phenotypes as some of these Tn mutants can obtain resources from other mutants in the pool. To prevent mutants from sharing cellular metabolites, a technique called *microfluidics* is used to encapsulate individual cells in a manner similar to that discussed for single-cell genomics in Section 10.11. In this way, cross-feeding is prevented, and previously unrecognized phenotypes can be detected.

With this background in functional genomics, we now switch gears to study how multiple—as compared to single—genomes can be studied simultaneously using a powerful form of omics that can reveal the diversity of single target genes or the entire genomic complement of virtually any environmental sample.

Check Your Understanding

- How can a gene essential to a bacterium’s survival be identified using Tn-Seq?

10.7 Metagenomics

Microbial communities contain many microbial species, many of which have never been cultured or formally identified. **Metagenomics** is the science that analyzes pooled DNA or RNA from an environmental sample containing organisms that have not been isolated and identified (Figure 10.17). Just as the total gene content of an organism is its *genome*, so the total gene content of a microbial community is its **metagenome** (Table 10.6). In addition to metagenomic analyses based on DNA sequencing, analyses based on RNA or proteins—metatranscriptomics (Section 10.8) or metaproteomics (Section 10.9), respectively—may be used to explore the patterns of gene expression in natural microbial communities. With today’s molecular technology, these studies can even be done on individual cells (Section 10.11).

Figure 10.16 Tn-Seq and fitness analysis of *Caulobacter crescentus* mutants during bacteriophage infection. (a) Electron micrograph of bacteriophage ϕCbK binding to the flagellated cell pole of a cell of *C. crescentus*. (b) Replication cycle of ϕCbK . ϕCbK adsorbs to the flagellum and pili of *C. crescentus* and then injects its genome through the bacteriophage-specific receptor. The host cell then replicates the ϕCbK genome and new viral particles are made prior to cell lysis. (c) A library of transposon (Tn) mutants (Section 9.11) is constructed and exposed to

increasing numbers of ϕCbK particles. These mutants contain a Tn that possesses terminal DNA sequences that are recognized by a special restriction enzyme (RE). This RE cuts the chromosomal DNA at sites outside of the Tn insertion. As the pool of Tn mutants is exposed to increasing concentrations of ϕCbK , mutants that are resistant to the bacteriophage survive at a greater rate and thus display increased fitness. Cell colors denote mutants in gene products necessary for the corresponding ϕCbK replication cycle in part b. (d) Tn-Seq analysis of Tn mutant pools following

infection with ϕCbK . Total DNA from the Tn mutant pools is extracted, cut with the RE mentioned in part c, and sequenced by next-generation methods. The chromosomal location of the Tn insertion site determined from sequencing is plotted versus the concentration of ϕCbK . The data show that phage receptor mutants are most resistant. Line colors correspond to Tn mutants in the ϕCbK replication cycle as depicted in part b. Data adapted from Christen, M., et al. 2016. *J. Mol. Biol.* 428: 419.

Examples of Metagenomic Studies

While several examples of metagenomic studies are presented in this text, two simple examples are highlighted here. Several environments have been surveyed by large-scale metagenome sequencing projects. Extreme environments, such as highly acidic runoff waters from mining operations (Section 22.2), tend to have low microbial species diversity. Consequently it has been possible to isolate

community DNA (and metabolites, Section 10.10) and assemble much of it into nearly complete individual genomes. Conversely, complex environments such as fertile soils or aquatic environments are much more challenging, and complete genome assemblies here are more difficult, yet possible (Section 19.8). A surprising finding that has emerged from metagenomic studies is that the majority of genes recovered from natural habitats do not originate from cells

(a)

(b)

Figure 10.17 Metagenomics and the microbiome. (a) Isolation, sequencing, and identification of DNA from a sample of seawater.

(b) *Proteobacteria* in the ocean. The distribution with depth of the major subgroups (alpha α , beta β , gamma γ , and delta δ) of *Proteobacteria* in the Pacific Ocean is shown. Many other types of bacteria are also present (not shown). Data adapted from Kembel, S.W., Eisen, J.A., Pollard, K.S., and Green, J.L. 2011. *PLoS One* 6: e23214.

but from viruses. This is discussed further in Chapter 11 where we consider the genomics and phylogeny of viruses.

Even if complete genomes cannot be assembled from environmental DNA, much useful information can be derived from metagenomic surveys (► Section 19.8). For example, environments can be analyzed for the presence and distribution of specific microbial groups. These vary greatly in relative abundance in different environments, and Figure 10.17b illustrates this for subgroups of *Proteobacteria* (a major phylum of gram-negative *Bacteria*, Chapter 16) at a sampling site in the Pacific Ocean near the Hawaiian Islands. Light, oxygen, nutrients, and temperature all change with depth in a water column, and these factors can be correlated with proteobacterial subgroups to show which are most competitive at each depth (Figure 10.17b). One curious observation that has emerged from such metagenomic studies is that much DNA in natural habitats does not reside in *living* cells. Around 50–60% of the DNA in the oceans is extracellular DNA present in deep-sea sediments. Presumably this was DNA deposited when dead organisms from the upper layers of the ocean sank to the bottom and lysed. Because nucleic acids are major reservoirs of phosphate, marine sediment DNA is thought to be a major component of the global phosphorus cycle.

Metagenomics and “Biome” Studies

The human body is estimated to contain about 10 trillion (10^{13}) cells, but each of us also carries around ten times more prokaryotic cells than human ones. This collection of prokaryotic cells is called the human *microbiome* (Chapter 24). Most of these organisms inhabit the large intestine, with the majority belonging to one of two phylogenetic groups of *Bacteria*, the *Bacteroidetes* and the *Firmicutes* (Chapter 16). A fascinating finding is that the

composition of the gut microbiome correlates with obesity in both humans and experimental mouse models. The data show that the higher the proportion of *Firmicutes* (mostly species of *Clostridium* and relatives) in the gut, the more obese is the human or mouse. A suggested mechanism that explains this finding is that fermentative species of *Firmicutes* convert more dietary fiber into fatty acids that can be absorbed by the host (► Section 24.9). In this way, the obese host gets more usable organic carbon than the thinner host from the same amount of food.

Recent surveys of the human and mouse gut microbiome have also revealed the rather surprising finding that over 60 species of fungi (eukaryotic microbes, Chapter 18) are present (Figure 10.18). These constitute the gut *mycobiome* (the prefix “myco” means fungal). Many fungi, typically nonpathogenic yeasts, inhabit the skin, the oral cavity, and virtually all moist surfaces on the human body. Many of these are common and generally harmless yeasts, such as *Saccharomyces*, *Cladosporium*, and most species of *Candida*. Most of these also are found in the gut, although some gut fungi—such as *Aspergillus* and *Trichosporon*—are potential serious pathogens (Chapter 34). Moreover, although gut fungi constitute less than 1% of the total human microbiome, it is known that certain conditions such as inflammatory bowel disease and some cases of obesity correlate strongly with specific fungal populations. Hence, metagenomics holds great promise for exploring possible connections between specific microbial populations and specific diseases in humans and other animals. Moreover, in cases where a clear cause-and-effect relationship is strongly suspected, metagenomics also holds great promise as a clinical tool for making medical diagnoses.

In the next two sections we travel beyond the genome to explore the technology for examining *gene expression*: omic methods that can reveal the RNAs and proteins encoded by the genome.

Figure 10.18 The mouse mycobiome. The data shown represent the relative amount of different fungal genera of the mouse intestine. The pie chart shows the most common fungi present are yeasts. Data adapted from Iliev, I.D., et al. 2012. *Science* 336: 1314.

- How is a metagenome analyzed?

10.8 Gene Chips and Transcriptomics

Once a genome sequence is available, the sequence can be used to synthesize miniature devices that can be used to detect genes from specific microbes, determine genome differences between closely related strains of the same species (for example, the presence of chromosomal islands), identify genome sequences that are bound by specific DNA-binding proteins, and measure gene expression. *Transcriptomics* refers to the study of a cell's global transcription and is done by monitoring the **transcriptome**, the total RNA generated under a chosen growth condition. Besides the aforementioned reasons for doing transcriptomics, the technique can also put a functional label on genes that have been annotated as simply encoding "hypothetical proteins." In these cases, discovering the *conditions* under which these genes are transcribed often yields clues to their function. Two main approaches are used in transcriptomics: *microarrays* and *RNA-Seq*.

Microarrays and the DNA Gene Chip

Microarrays are small, solid supports to which genes or, more often, oligonucleotides corresponding to segments of genes are fixed and arrayed spatially in a known pattern; they are often called **gene chips** (Figure 10.19a). Microarrays measure the DNA or RNA that hybridizes to the DNA sequences on the chip. When DNA is denatured (that is, the two strands are separated), the single strands can form hybrid double-stranded molecules with other nucleic acid molecules by complementary or almost complementary base pairing (Figure 10.19b; ► Section 12.1). This process is called *nucleic acid hybridization*, or **hybridization** for short, and is widely used in detecting, characterizing, and identifying segments

of DNA or RNA. The single-stranded segments of nucleic acid, whose identity is already known, are called **nucleic acid probes** or, simply, *probes*. To detect hybridization to the probes, the nucleic acid added to the chip must be labeled with a fluorescent dye and then the hybridized chip is scanned with a laser fluorescence detector that measures which of the probes contain hybridized DNA (Figure 10.19b, c).

Gene chips are typically about 1 to 2 cm and are inserted into a plastic holder that can easily be manipulated (Figure 10.20a); each chip holds thousands of different DNA fragments in a known order. In practice, each gene is usually represented more than once in the array to increase reliability. Whole genome arrays contain DNA segments that cover the entire genome of an organism. For example, a chip that covers the entire human genome (Figure 10.20a) can analyze over 47,000 human transcripts and has room for 6500 additional oligonucleotides for use in clinical diagnostics.

Measuring Gene Expression and Other Uses of Gene Chips

In a gene expression microarray, the probes are designed and synthesized for each gene based on the genomic sequence. Once attached to the solid support, the DNA segments can be hybridized with labeled RNA from cells grown under specific conditions, and the microarray is then scanned and analyzed by computer. Because mRNA levels are typically too low for use directly, the mRNA

Figure 10.19 DNA chip design and application. (a) DNA chip design. Short single-stranded oligonucleotides (probes) corresponding to each gene in an organism or to diagnostic sequences corresponding to numerous organisms are synthesized and affixed at known locations to make a microarray. (b) Microarray hybridization. The presence of specific DNA or RNA (in the form of cDNA) is assayed by hybridizing fluorescently labeled samples (DNA or cDNA) to the DNA probes on the chip. Labeled DNA or cDNA will bind to the probes on the chip if they possess sequence complementarity. (c) Analysis of microarray hybridization. A scanning laser is used to identify regions of the chip where labeled nucleic acid has bound to the probes.

Figure 10.20 Using gene chips to assay gene expression. (a) The human genome chip contains over 47,000 gene fragments. Blowup from part a to part b indicates location of actual microarray. (b) A hybridized yeast chip shows fragments from a quarter of the genome of baker's yeast, *Saccharomyces cerevisiae*. Each gene is present in several copies and has been probed with fluorescently labeled cDNA (derived from mRNA) from yeast cells grown under a specific condition. The background of the chip is blue. Locations where the cDNA has hybridized are indicated by a gradation of colors up to a maximum number of hybridizations, which shows as white. Because the location of each gene on the chip is known, when the chip is scanned, it reveals which genes were expressed.

sequences are first amplified and converted into DNA using a modified version of the polymerase chain reaction (PCR) that converts RNA to *complementary DNA* (cDNA, ► Section 12.1).

To monitor global gene expression, total RNA (or cDNA) from a test sample is hybridized to an array of oligonucleotides corresponding to the entire genome. Figure 10.20b shows part of a chip containing probes for over 6000 protein-encoding genes of the yeast *Saccharomyces cerevisiae*. After hybridizing yeast cDNA to the chip, a distinct hybridization pattern is observed, and the fluorescence and its intensity reveal both which genes were expressed and at what level (Figure 10.20b); these data yield the *transcriptome* of the yeast culture grown under specified conditions (Table 10.6). Using such analyses, gene expression under different growth conditions can be measured. For example, in yeast—which can grow by either fermentation or respiration (Chapter 3)—transcriptome analyses have shown that genes that control production of ethanol (a key yeast fermentation product) are strongly repressed while genes encoding citric acid cycle functions (needed for aerobic growth) are strongly activated when the organism is shifted from fermentative to respiratory conditions. Overall, over 700 genes are turned on and more than 1000 turned off during this metabolic transition. In “shift” experiments of this type, the expression pattern of genes of unknown function is also revealed, and analysis of these expression patterns sometimes yields valuable clues to the cellular function of these unknown proteins.

Microarrays can also be used to identify specific microbes. For example, identification (ID) chips have been used in the food industry to detect DNA sequences unique to specific pathogens, such as the gastrointestinal pathogen *Escherichia coli* O157:H7 (Table 10.1), an occasional foodborne pathogen (► Section 33.11). In environmental work, microarrays called *PhyloChips* have been used to assess microbial

diversity. These contain oligonucleotides complementary to the 16S rRNA of different bacterial species, a molecule widely used in microbial systematics (► Sections 13.11 and 13.12). After extraction of bulk DNA or RNA from an environment, the presence or absence of a given species can be assessed by the hybridization response on the chip (► Section 19.7). Although ID chips and PhyloChips can be made highly specific, the inexpensive nature of DNA isolation, sequencing, and analysis have made metagenomic approaches (Section 10.7) to the identification of specific pathogens or phylogenetic groups in natural samples the preferred method of assessment.

RNA-Seq Analysis

RNA-Seq analysis is a transcriptomic method in which all the RNA molecules from a cell are converted to DNA (cDNA, ► Section 12.1) and then sequenced. Provided that the genome sequence is available for comparison, RNA-Seq reveals both which genes were transcribed and how many RNA copies of each gene were made. Because RNA-Seq targets *all* transcripts, it is ideal for measuring the expression of mRNA, to identify long untranslated regions, and to discover noncoding RNAs. RNA-Seq requires high-throughput sequencing (second-generation sequencing, Section 10.2) and is complicated a bit by the fact that the most abundant RNA in a cell is ribosomal RNA (rRNA). Nevertheless, methods are available to remove rRNA or enrich mRNA and primary transcripts from a total RNA pool. In addition, recent advancements in sequencing technology may allow sequencing without removing rRNA.

RNA-Seq has overtaken microarray analysis as the method of choice for global studies of gene expression. The data from transcriptomic experiments can be presented in the form of a *heat map*, which uses different colors to show the level of gene expression. For example, Figure 10.21a identifies gene clusters that are upregulated (more

(a)

(b)

Figure 10.21 RNA-Seq analysis of the heterocyst-forming cyanobacterium *Anabaena* during nitrogen starvation. Cyanobacteria are oxygenic phototrophs and only some species, such as those that form heterocysts, can fix nitrogen under fully oxic conditions. (a) Heat map of gene expression 6, 12, and 21 h after cells were starved for fixed nitrogen. Genes that display increased expression are in red, whereas those that display decreased expression are in blue. Gene clusters 1–4 all encode proteins linked to nitrogen fixation. (b) Mapping of RNA-Seq reads. The arrows indicate the annotated open reading frames, and the plots underneath correspond to the number of sequencing reads detected for each chromosomal nucleotide position. Note that the negative numbers represent chromosomal positions upstream of the predicted start codon for the genes. The genes *psbB* and *petF* encode key proteins of photosynthesis, and *nrrA* encodes a protein that regulates heterocyst formation (the heterocyst is the site of N_2 fixation, ◀ Section 3.12). The pigments, diversity, and general biology of cyanobacteria are discussed in Sections 14.3, 14.4, 14.6 and 15.3. Parts a and b modified from Flaherty, B.L., F. van Nieuwerburgh, S.R. Head, and J.W. Golden. 2011. *BMC Genomics* 12: 332.

intensely transcribed) during nitrogen deprivation in the heterocyst-forming cyanobacterium *Anabaena*, a phototroph that can use N_2 as its nitrogen source (nitrogen fixation, ◀ Section 3.12). Gene clusters 1–4 represent increased expression of nitrogen fixation and heterocyst formation genes (heterocysts are the site of N_2 fixation) as the time of nitrogen deprivation increases (Figure 10.21a). RNA-Seq data can also be used for transcript mapping by plotting the sequences read against the genome annotation. Figure 10.21b illustrates the sequencing coverage at each base along the open reading frame regions for *psbB*, *petF*, and *nrrA*, genes that encode two key proteins needed for photosynthesis and a regulator protein for heterocyst formation in *Anabaena*, respectively (◀ Section 8.9). These plots demonstrated long 5' untranslated regions present in these transcripts, which may be sites where specific DNA-binding proteins attach in regulatory events (Chapter 7).

Transcript abundance under different culture conditions can also be analyzed using RNA-Seq data, as indicated by a comparison of cultures of a *Clostridium* species in exponential and stationary phase (Figure 10.22). Clostridia are gram-positive bacteria that produce endospores, the highly resistant and dormant stage of the cell's life cycle (◀ Section 2.8); the general properties of sporulating clostridia are discussed in Section 16.8. As one might predict, transcription of genes of the glycolytic pathway (the major means by which the organism makes ATP) is elevated during exponential growth, whereas expression of sporulation genes increases in stationary phase, when nutrients become limiting (◀ Section 8.6). RNA-Seq is also being used for microbial community analysis and can provide information on relative transcription levels when a genome sequence is not available for comparison. In this case the sequences detected must be identified by homology with sequences present in databanks.

As discussed in Section 10.7, metagenomics is the genomic analysis of pooled DNA or RNA obtained from organisms in an environment. Metagenomic analysis using RNA-Seq can be exploited for culturing microbes from nature that had previously resisted

Figure 10.22 Transcriptomic analysis of sporulation genes in *Clostridium*. RNA-Seq analysis of cultures of a *Clostridium* species grown for 4.5 h (cells in exponential phase) or 14 h (cells in stationary phase). Two genomic regions are shown: (left) ~5.4-kb segment surrounding the *gap-pgk-tpi* glycolytic operon, and (right) ~1.2-kb segment surrounding the *cotJC-cotJB* sporulation operon. Production of endospores is triggered by nutrient starvation. Data from Wang, Y., X. Li, Y. Mao, and H.P. Blaschek. 2011. *BMC Genomics* 12: 479.

laboratory culture. This can be accomplished by using RNA-Seq to identify highly transcribed genes in the microbial community that contain the microbe of interest, followed by sequence analyses to identify the proteins encoded by the highly transcribed genes. These data can be used by microbiologists to deduce which nutrients the microbe is most likely using given the predicted enzymatic activities of these proteins. Culture media can then be devised using this information as a guide to successfully culture the previously uncultured.

We transition now from nucleic acid analyses to protein analyses to reveal the importance of other omics to modern-day microbiology and biology in general.

10.9 Proteomics and the Interactome

The genome-wide study of the structure, function, and activity of an organism's *proteins* is called **proteomics**. The number and types of proteins in a cell change in response to the cell's environment or other factors, such as developmental cycles. As a result, the term **proteome** has unfortunately become ambiguous. In its wider sense, a proteome refers to *all* the proteins encoded by an organism's genome. In its narrower sense, however, it refers to those proteins present in a cell *at any given time*. The term **translatome** has also been used to describe the latter; that is, it refers to every protein made by a cell *under specific conditions*. Recall from Chapter 7 that the extensive regulatory systems of *Bacteria* and *Archaea* tightly control which proteins are made under any given set of nutrients and environmental conditions. An understanding of which proteins are synthesized under a given set of conditions—the goal of proteomics—complements transcriptomics data and is the “gold standard” for confirming that a transcript detected by transcriptomics was actually translated.

Methods in Proteomics

To identify individual proteins within a mixed pool of proteins, proteomics relies on some form of *mass spectrometry*, a method that can also be used to identify metabolites (Section 10.10). The mass of ^{12}C is defined as exactly 12 molecular mass units (daltons). However, the

masses of other atoms, such as ^{14}N or ^{16}O , are not exact integers. Mass spectrometry using extremely high mass resolution techniques, which can distinguish between slightly different mass-to-charge ratios, allows the unambiguous determination of the molecular formula of any small molecule. Thus mass spectrometry can be used to identify the amino acid sequence of several peptides in a sample.

Figure 10.23 illustrates a standard proteomic analysis, which begins with extraction of total protein from a sample. To increase sensitivity, liquid chromatography is typically used to separate protein mixtures. In high-pressure liquid chromatography (HPLC), a protein sample is dissolved in a suitable liquid and forced under pressure through a special column that separates proteins by differences in their chemical properties, such as size, charge, or hydrophobicity. Fractions are collected at the end of the column, the proteins in each fraction are digested by protease enzymes, and the resulting peptides are identified by mass spectrometry. The amino acid sequence of these peptides can then be searched against the translation of a genome to identify the presence of specific proteins (Figure 10.23).

MALDI (*matrix-assisted laser desorption ionization*) is an advanced version of mass spectrometry that does not require the protein separation and digestion step (Figure 10.23). Instead the sample is affixed to a matrix and then ionized and vaporized by a laser (Figure 10.24). The ions generated are accelerated along the column toward the detector by an electric field. The time of flight (TOF) for each ion depends on its mass/charge ratio—the smaller this ratio, the faster the ion moves. The detector measures the TOF for each ion, and the computer calculates the mass and hence the molecular formula. The combination of these two techniques is known as *MALDI-TOF*.

Utility of Proteomics: Profiling Protein Modifications

Not only can proteomics identify proteins that are abundant under certain growth conditions, but it can also be modified to detect post-translational modifications (◀ Section 7.16). For example, because mass spectrometry spectra are known for all proteins of the *Mycobacterium tuberculosis* (the causative agent of tuberculosis, ▶ Section 31.4) proteome, additional chemical groups attached to peptides can also be identified. These chemical modifications include phosphorylation, glycosylation, methylation, pupylation (addition of a ubiquitin-like molecule), lipidation, and acetylation.

Figure 10.25 illustrates the modified proteome of *M. tuberculosis* and the role of the modified proteins in the phenotype of the pathogen. This analysis shows that some modifications can be enriched in functional categories, such as lipidation of proteins that

Figure 10.23 Proteomics. Total protein is isolated from a culture or environmental sample. This protein pool is converted to fractions of small peptides using various denaturation, separation, and digestion methods. Following ionization of the peptide fractions, the ions are characterized using mass spectrometry (M.S.). Peaks from the M.S. are compared to standards, and the primary amino acid sequence of the resulting peptides is identified and quantified. The M.S. peaks can also be used to determine if the peptides possess post-translational modifications (◀ Section 7.16 and see Figure 10.25).

Figure 10.24 MALDI-TOF mass spectrometry. In matrix-assisted laser desorption ionization (MALDI) spectroscopy, the sample is ionized by a laser and the ions travel down the tube to the detector. The time of flight (TOF) depends on the mass/charge (m/z) ratio of the ion. The computer identifies the ions based on their time of flight, that is, the time it takes to reach the detector.

participate in cell wall biosynthesis (the cell wall of *M. tuberculosis* contains an abundance of lipids that assist in its virulence and play a major role in its acid-fast staining properties, ► Sections 16.11 and 31.4). Pupylation, first discovered to occur in *Bacteria* by studying *M. tuberculosis*, is believed to direct proteins to a cellular degradation pathway and is enriched with proteins associated with virulence and metabolism. These protein modifications may play a role in the pathogenesis of *M. tuberculosis* as well as the host's immune response during infection by engaging eukaryotic cell receptors or antigen processing pathways. By studying the modified proteome, immunologists may also be able to identify novel epitopes (portions of an antigen where antibodies attach) as vaccine candidates (► Section 28.3).

While proteomic analyses can be performed on pure cultures of specific microbes, *metaproteomics* of environmental samples are particularly insightful for revealing the collective metabolic potential of a microbial community. As will be illustrated in Chapter 19, metaproteomics combined with metagenomic and metatranscriptomic approaches can provide a snapshot of ongoing physiological processes in a microbial community and highlights the power of omics for answering the key questions about the community of “who’s there” and “what are they doing” (► Figure 19.8).

The Interactome

By analogy with the terms genome and proteome, the **interactome** is the complete set of *interactions* among the macromolecules within a cell (Figure 10.26). Originally, the word *interactome* was applied only to interactions between proteins, many of which assemble into complexes. However, it is also possible to consider interactions between different classes of macromolecules, such as between protein and RNA (see the protein–RNA interactome in Figure 10.34b).

Interactome data are typically expressed in the form of network diagrams, with each node representing a protein and the connecting lines representing the interactions. Diagrams of whole interactomes

Figure 10.25 Modified proteome of *Mycobacterium tuberculosis*. *M. tuberculosis* is the causative agent of the human disease tuberculosis, and its biology is discussed in ► Sections 16.11 and 31.4. Post-translational modifications (► Section 7.16) found on different categories of *M. tuberculosis* proteins. The “*M. tuberculosis* specific” category of proteins were first detected in *M. tuberculosis* and possess conserved Pro-Glu/Pro-Pro-Glu amino acid sequence motifs (Section 10.12). Many of these *M. tuberculosis*-specific proteins are believed to be secreted into host cells because they contain an N-terminal signal sequence (► Sections 6.12 and 6.13). Data adapted from Banaei-Esfahani, A., Nicod, C., Aebbersold, R., and Collins, B.C. 2017. *Curr. Opin. Microbiol.* 39: 64.

Note the six small networks that fall outside the single large network.

can be extremely complex (see Figure 10.33), and thus more focused interactomes, such as the motility protein network from the bacterium *Campylobacter jejuni* (Figure 10.26), are more instructive. This figure shows the core interactions between well-known components of the chemotaxis system (◀ Sections 2.11 and 7.6), including all other proteins that are known to interact with these.

There is an omics that deals specifically with metabolism, and we tackle that next.

Check Your Understanding

- Why is the term “proteome” ambiguous, whereas the term “genome” is not?
- What are the most common experimental methods used to survey the proteome?
- What is the interactome?

10.10 Metabolomics

The **metabolome** is the complete set of *metabolic intermediates* and small molecules produced by an organism. In other words, the

metabolome reflects the enzymatic pathways encoded by the genome. While transcriptomics and proteomics point to the activity of specific pathways, metabolomic data confirm that these potential reactions and pathways are actually occurring in the cell at any given time or under any given set of conditions.

Advances in Metabolomic Techniques: NIMS

Metabolomics has lagged behind other omics due largely to the immense chemical diversity of small metabolites present in cells (Chapters 3 and 14). This makes systematic metabolomic screening technically challenging. Early attempts used nuclear magnetic resonance (NMR) analysis of extracts from cells labeled with ^{13}C -glucose (^{13}C is a heavy isotope of carbon, most of which is ^{12}C). However, this method is limited in sensitivity, and the number of metabolites that can be identified in a mixture simultaneously is too low for resolution of complete cell extracts.

While MALDI-TOF mass spectrometry (Section 10.9) can be used to detect and identify metabolites, nanostructure-initiator mass spectrometry (NIMS) is a more useful technique that can directly analyze biological samples without the need for special analytical preparation (Figure 10.27). Thus biofluids, tissues, cultures, or even individual cells can be analyzed. In NIMS, a laser is used to ionize the sample—just as in MALDI-TOF—but the silicon-coated surface used in NIMS does not generate the background interference seen during ionization of a matrix by MALDI-TOF. This allows for the accurate identification of small metabolites present at low concentrations and increased spatial resolution during tissue imaging. Modifications to the silicon surface can also be made to detect notoriously difficult molecules, such as structurally similar carbohydrates or steroids. These traits also make NIMS more sensitive than MALDI, which is illustrated by the ability of NIMS to detect a specific drug in a single human cell in the yoctomole (10^{-24} M) range (Figure 10.27).

Figure 10.27 NIMS identification of metabolites. In nanostructure-initiator mass spectrometry (NIMS), a cell is placed on the silicon initiator surface and vaporized using a laser. The resulting ionized metabolites within a single cell are then detected using mass spectrometry as indicated by the mass-to-charge plots. Peak 342 represents the metabolite propafenone (1 yoctomole = 1×10^{-24} mole). Because NIMS lacks a matrix, it has extremely high sensitivity and resolution. Ionized metabolites are represented rising from the surface.

Utility of Metabolomics

Metabolome analysis has been particularly useful for the study of plant biochemistry, since plants produce several thousand different metabolites—more than most other types of organisms. These compounds include many so-called *secondary metabolites*, chemicals such as scents, flavors, alkaloids, and pigments, many of which are commercially important. Metabolomic investigations have monitored the levels of several hundred metabolites in the model plant *Arabidopsis*, and significant changes were observed in the levels of many of these metabolites in response to changes in temperature, an alarming hint that global climate change will likely alter plant metabolism in major ways. Metabolomics can also be done on microbial cultures as well as natural microbial communities such as biofilms (◀ Sections 4.9 and 8.10; ▶ Section 20.4). For example, microbiologists have detected over 3500 different metabolites in a relatively simple microbial biofilm growing in extremely acidic (pH ~0.9) and heavy-metal-rich water draining from an abandoned iron mine site in northern California (USA). Many of these metabolites were suspected of being osmolytes and other protective molecules used by the microbial community inhabiting the runoff for combating the osmotic and other life stressors in this extreme environment.

Metabolomics has also been deployed to help characterize the human microbiome (Chapter 24). For instance, our skin epidermis is composed not only of human cells but also of microbes that contribute to epithelial health. Thus metabolites formed by skin cells, associated microorganisms, and personal hygiene products are present. **Figure 10.28** shows results of an actual study of the pattern of metabolites and microbial diversity on the skin of a human male and a female plotted simultaneously on a three-dimensional topographical heat map of the human body. One of the goals of this type of research is to determine if the presence of particular metabolites can be linked to the presence of particular microbial species. Such a picture of the human skin could offer microbiologists as well as medical clinicians a better understanding of the diversity and ecology of the skin microbiome and pave the way for the future use of studies of this type in the diagnosis of skin health or disease.

As expected, the omics study of the skin (Figure 10.28) revealed many microbes known from previous studies of the skin microbiome (▶ Section 24.5). But the study also discovered a diverse mixture of metabolites. While common chemicals produced by human skin cells such as triacylglycerides and diacylglycerides were readily detected, various metabolites resulting from microbial processing of these compounds were also detected. Overall, the level of metabolite diversity detected on specific areas of the body did not correlate well with microbial diversity. Instead, the complexity of the human skin metabolome significantly exceeded the diversity of the microbial profile, and this indicates that each species is likely producing several distinct metabolites. Interestingly, and somewhat surprisingly, the results also showed that personal hygiene products are a major source of metabolites on human skin.

Throughout this chapter we have discussed various omics and their applications as more or less individual entities. We now shift our focus to integrating multiple omics to better understand the entire organism—the major goal of systems biology.

Figure 10.28 Metabolomic and metagenomic mapping of skin. Three-dimensional heat maps represent the diversity of metabolites and microorganisms detected on various areas of the skin on a human male and a female. Red indicates the highest level of diversity and purple indicates the lowest level of diversity.

III • Systems Biology

The many omics born from the genomics revolution have been used in concert to attack complex problems in both single cells and entire microbial communities. The omics complement each other in ways that allow scientists to develop models that can be tested by laboratory experimentation.

The basic strategy of **systems biology** is to generate comprehensive models for predicting the behavior or properties of an organism that were not obvious from pre-omics era observations. These are referred to as the *emergent properties* of the organism. Understanding an organism's emergent properties provides a deeper insight into its overall biology than can any single omics study by itself. Systems biology integrates the numerous omic datasets covered in Part II of this chapter to create insightful models of the biological workings of an individual organism or an entire microbial community (**Figure 10.29**). We begin by seeing how all of these can come together in ecological studies of individual cells in a microbial community.

Figure 10.29 The components of systems biology. (a) The results of various “omics” analyses are combined and successively integrated into higher-level views of the entire biology of a pure culture, such as (b) that of the green sulfur bacterium *Chlorobium*; or of a mixed microbial community, such as (c) that of phototrophic sulfur bacteria obtained from a lake; or of a single cell isolated from a microbial community (see Figure 10.30).

10.11 Single-Cell Genomics

Besides sequencing total environmental DNA as described for metagenomics (Section 10.7), the genomes of individual cells can also be sequenced—a technique called *single-cell genomics* (SCG) (Figure 10.30). This is possible because of the ability to amplify tiny amounts of DNA. Single-cell genomics is critical for studying the metabolic potential of microorganisms in natural microbial communities. While metagenomic analysis of a microbial community can detect the presence of genes specific to certain pathways, it is difficult to discern whether the pathways are contained within the same organism. Besides genome sequencing, transcriptome and proteome analyses can also be performed on individual cells, leading to a comprehensive omics study on one component of a microbial ecosystem.

Cell Isolation and Sample Preparation

The ability to isolate cells is obviously essential for single-cell genomics, and various physical techniques including dilution in microwells (► Section 19.3), encapsulation, and fluorescence-activated cell sorting (FACS) have been used to do so. For encapsulation, the sample is diluted and added to sterile oil to form microdroplets. Approximately 30% of the resulting droplets from

this technique will contain only one cell (Figure 10.31). Combining droplet encapsulation with FACS, which is able to optically detect single cells, allows droplets that do not contain a cell to be rejected. This method of single-cell isolation has also been shown effective in isolating single virions for viral omics analyses.

Sequencing DNA from single cells relies on a modified version of the polymerase chain reaction (PCR, ► Section 12.1) called *multiple displacement amplification* (MDA) (Figure 10.31; ► Section 19.12 and Figure 19.43). This PCR technique uses a highly sensitive viral DNA polymerase to amplify the femtogram (10^{-15} g) quantities of DNA present in a single bacterial cell into the micrograms (10^{-6} g) of DNA required for sequencing (a billionfold amplification). However, because of its very sensitivity, contamination is one of the biggest problems with MDA. Contaminating DNA can originate from the sample itself or from the laboratory equipment and reagents. If great care is not taken in isolating the cell and amplifying its genome, contaminating DNA can make up half or more of the reaction products and create major problems for genome assembly and further genomic analyses. In addition to analysis of a cell’s genome, its RNA can also be analyzed using RNA-Seq following amplification to form cDNA by a modified version of PCR (Section 10.8). Single-cell proteomic analyses are trickier than

Figure 10.30 Single-cell genomics. A single cell isolated from an environmental sample can be the source of a diversified omics study. MDA, multiple displacement amplification (► Section 19.12).

Figure 10.31 Isolation and sequencing of single cells. Droplets of a diluted sample are added to microfluidic wells at a concentration such that a single well will contain no more than a single cell. Wells containing cells are then subject to multiple displacement amplification (MDA) for DNA sequencing.

nucleic acid studies because amplification is not employed, but analyses using extremely sensitive fluorescence methods are available for this purpose (Figure 10.30).

Applications of Single-Cell Omics

Single-cell omics have the unique power to probe several facets of an organism's biology in an individual cell rather than on a cell population basis. Using SCG, metabolic genes present in a microbial community (Figure 10.29c) not only can be identified but can be assigned to particular species; such information reveals which particular organisms are degrading which particular nutrients. For example, single-cell genomics has been used to analyze hydrocarbon degradation by bacteria in polluted environments, leading to a better understanding of which organisms are doing what in the overall process. Similarly, plasmids and viruses can be allocated to their correct host when the genome of a single cell is sequenced.

Single-cell genomics has also been used to explore the genomes of phyla of *Bacteria* and *Archaea* that are detected in environmental 16S rRNA gene surveys but for which no laboratory cultures are available (these are called *candidate phyla*, ► Section 13.12). Collectively, these yet-to-be-cultivated microbes have been called *microbial dark matter*. One dark matter study applied SCG to over 200 uncultivated archaeal and bacterial cells from nine different environments. The results revealed several surprising findings including the following: Some archaeal RNA polymerase sigma factors are similar to their bacterial counterparts (◄ Sections 6.5 and 6.6); some mRNA stop codons (◄ Section 6.9 and Table 6.4) have been reassigned to incorporate actual tRNAs with their attached amino acids; the genomes of some bacterial cells encode an oxidoreductase enzyme previously seen only in eukaryotes; some *Archaea* contain genes encoding a bacterial-like stringent response (◄ Section 7.9); and some *Archaea* produce an enzyme that functions in peptidoglycan synthesis (recall that peptidoglycan is a “signature molecule” of

Bacteria and is not known from any *Archaea*, ◄ Section 2.3). Many other examples have emerged as well.

Single-cell genomics is an excellent example of serendipity, the “pleasant surprise” of finding one thing while working on another. In this case, the serendipity occurred when omic methods designed with one goal in mind—analysis of the biology of *cell populations*—were refined to probe the biology of a *single cell* in ways never before thought possible. Single-cell genomics is poised to complement the *Earth Microbiome Project*, a sequencing endeavor to archive the genome sequence of all cultured bacterial and archaeal type strains (<http://www.earthmicrobiome.org/>). For those species of *Bacteria* and *Archaea* that reside in the microbial dark matter, SCG offers a way to include these species in the archive while simultaneously revealing valuable clues that will one day bring these organisms into laboratory culture.

We close out this chapter with two final sections, each focused on combining previously discussed omics methods to solve a specific problem. The first section explores the system biology of a notorious bacterial pathogen, whereas the second section is devoted to the entire human body.

Check Your Understanding

- How are single cells isolated from a mixed population?
- What must be done before minute amounts of DNA can be sequenced?

10.12 Integrating *Mycobacterium tuberculosis* Omics

Mycobacterium tuberculosis is a pathogen that infects one-third of the world's population and kills approximately 2 million people every year (► Section 31.4). Multidrug resistance and the ability to temporarily enter dormancy in response to stress (◄ Section 8.12) are two characteristics that contribute to the persistence of *M. tuberculosis*. Thus, the identification of new treatment methods is critical for combating *M. tuberculosis*. This challenge is being tackled using a systems biology approach to understand how *M. tuberculosis*—an intracellular pathogen—adapts to the oxygen deficiency (hypoxia, a condition that develops in tuberculosis) in host cells and to identify potential drug targets for therapeutic design.

Tuberculosis Gene Expression and Regulatory Networks

As we discussed in Section 10.8, RNA-Seq can be used to characterize an organism's complete expression profile. A modification of this technique termed *dual RNA-Seq* can be used to simultaneously profile the transcriptomes of a pathogen *and* its host cell. This approach allows for the responses of both the pathogen and host to be captured during the infection process and has been especially useful for understanding how *M. tuberculosis* evades the host's defense systems. Data from dual RNA-Seq and the integration of over 600 separate expression experiments have facilitated the construction of gene expression models. These models have identified the primary energy source of intracellular *M. tuberculosis* cells as host cholesterol, and they have shown that the amino acid aspartate produced by the host is used by *M. tuberculosis* not only as a nitrogen source but also as

Figure 10.32 Genes controlled by the regulators LexA and DevR in *Mycobacterium tuberculosis*. (a) A snapshot of the interactome of some of the gene clusters that participate in DNA repair as identified from their expression pattern. Members of the LexA regulon are in red, while green connectors indicate interactions of other DNA repair genes. (b) Colorized scanning electron micrograph of cells of *M. tuberculosis*. (c) Venn diagram of results of various studies of the DevR regulon. Three methods of assessing genes in the regulon were employed and the number of genes identified from each detection method is indicated. A total of 622 genes were identified by ChIP-Seq analysis; of these, only 37 were identified by every method. Data adapted from van Dam, J.C.J., et al. 2014. *BMC Syst. Biol.* 8: 111.

protection against reactive oxygen species (◀ Section 4.16) produced by macrophages (a type of phagocytic cell, ▶ Section 26.1) trying to kill *M. tuberculosis* cells.

The *M. tuberculosis* research has integrated transcriptome and other omics datasets including ChIP-Seq, a method where an antibody that combines with a specific DNA-binding protein is used to trap the protein bound to its DNA, after which the DNA is removed and sequenced. From ChIP-Seq analyses, several transcription factors and regulatory networks critical to the pathogenesis of *M. tuberculosis* have been identified. These include regulation by the major bacterial cell regulator LexA (◀ Section 9.4) of certain genes for DNA damage response, and control by members of the DevR regulon of the entry of *M. tuberculosis* into dormancy (Figure 10.32). Additional potential drug targets have also been identified through the screening of over 1000 different mutant strains of *M. tuberculosis*. This analysis mapped 18 previously uncharacterized genes to the persistence response of *M. tuberculosis* (◀ Section 8.12), illustrating the power of integrating omics with mutant analyses to identify important pathogenicity genes in *M. tuberculosis*.

Tuberculosis Proteomics and Metabolomics

As was illustrated in Figure 10.25, proteomics has been used to identify *M. tuberculosis* protein modifications under certain conditions. The power of proteomics has been used to identify proteins essential to the *M. tuberculosis* hypoxia response. While expected proteins that combat reactive oxygen species such as superoxide dismutase (◀ Section 4.16) were detected, so were toxin–antitoxin systems (◀ Section 8.12) and proteins that participate in the biosynthesis of the unique lipoproteins of the *M. tuberculosis* cell envelope (▶ Section 16.11). Production of nitrate and nitrite transporters also increased as *M. tuberculosis* switched to anaerobic respiration

(◀ Section 3.10) for energy metabolism. Moreover, at least 160 different uncharacterized proteins containing the N-terminal amino acid sequence “Pro-Glu/Pro-Pro-Glu” (amino acids and their abbreviations are listed in Figure 6.27) were detected in the pathogen. If drugs could be developed that specifically target this peptide, they might be effective treatments for tuberculosis.

Online fundraising and social media have even been combined for the common goal of identifying new drugs to treat tuberculosis. The *Connect to Decode* initiative (<http://c2d.osdd.net>) is composed of more than 800 researchers whose collective goal is to identify new tuberculosis drug targets by mapping the entire interactome of *M. tuberculosis*. By analyzing over 10,000 *M. tuberculosis* experimental datasets, the researchers have now annotated 87% of the proteins encoded by the genome. This is a vast improvement over the 52% of genes annotated in the original genome sequence. This collective effort has also resulted in a map of the complete *M. tuberculosis* interactome, with over 1400 proteins connected by more than 2500 functional relationships (Figure 10.33). Thus far, nearly 20 potential drug targets and their interactomes have been identified by this initiative. These targets lack homology to human proteins or to proteins of the human oral and gastrointestinal microbiome, thus increasing the probability of identifying drugs with the least side effects.

While tuberculosis metabolomics is in its infancy, studies comparing virulent versus attenuated *Mycobacterium* strains have identified over 1000 different lipids—many of them unique lipoproteins—that are likely quite important to the biology of *M. tuberculosis*. Thus, the *M. tuberculosis* lipid metabolism proteome may reveal several potential therapeutic targets for tuberculosis. Finally, by profiling the *secretome* (an inventory of metabolites secreted) of *M. tuberculosis*, molecules unique to virulent strains (such as the nucleotide

Vashisht, R. et al. 2012. PLoS One 7 (7): e39809

Figure 10.33 *Mycobacterium tuberculosis* protein interactome. Node color indicates proteins of the same category, connecting lines indicate interactions, and node size indicates relative number of interactions.

1-tuberculosinyladenosine) have been discovered. This modified nucleotide is present in the urine of humans infected with *M. tuberculosis*, and its discovery illustrates the power of omics to link a particular pathogen to a specific molecule—be it a gene, protein, or metabolite—and yield new disease markers for use in clinical diagnostics. Moreover, if this modified nucleotide turns out to be essential to the survival of *M. tuberculosis* cells, drugs that interfere with its synthesis or activity are potential anti-tuberculosis drugs.

- How has systems biology provided new approaches to treating the disease tuberculosis?

10.13 Systems Biology and Human Health

In 2003 the sequence of the 3-billion-base-pair human genome was completed and released in an international effort that cost nearly \$3 billion. With the advent of next-generation sequencing, the cost to sequence a human genome has fallen under \$1000, triggering an onslaught of human genome sequence data. How can the human genome and systems biology be tailored to benefit human health? By comparing genome sequences in over 2500 people from different continents, scientists have already identified over 88 million sites in the human genome that are subject to variation. These genomic variants include single nucleotide differences, insertions and deletions, and rearrangements, each of which may turn out to be harmless, to be beneficial, to contribute to noninfectious “lifestyle”

diseases such as obesity, diabetes, and heart disease, or to govern susceptibility to certain cancers. Understanding if and how genomic variants contribute to disease can be used to improve diagnostics, treatments, and prevention.

The omics revolution has opened the era of *personalized medicine*, where genomic, transcriptomic, proteomic, metabolomic, and pharmacogenomic (omics responses to drugs) data are exploited to generate a snapshot of normal and disease states along with immune processes that occur in between. The first step in personalized medicine is the generation of an *integrative Personal Omics Profile* (iPOP). Tracking changes in this profile during healthy and disease states can aid in assessing medical risks and diagnosing and treating patients. The utility of personalized medicine can be illustrated by an actual study where blood samples taken from a male subject 20 times over a period of two years were subjected to proteomic and metabolic profiling of about 5000 proteins and 4000 metabolites (**Figure 10.34**). The results suggested that the subject was at risk for coronary artery disease—which was not surprising based on his medical history and familial incidence—but also indicated that he was at high risk for type 2 diabetes. While this was a surprising finding considering his overall condition and familial health history, the

Figure 10.34 An integrated personal omics profile (iPOP). (a) Partial heat map of RNA and protein expression. Data plotted are from days 294–400 of the two-year study, with an increase in RNAs and proteins related to diabetes spiking on day 307. (b) Glucose regulation interactome. RNAs are indicated with blue circles, proteins with yellow squares, and RNA and its corresponding protein with green hexagons. A metabolite from the interactome is also shown. (c) Blood glucose levels during the time course of the study. The time of contracting a respiratory virus (RSV) is indicated as well as the time frame in which the patient made lifestyle and diet changes. Parts b and c adapted from Jennifer Li-Pook-Tham and Michael P. Snyder, Stanford University.

prediction was based on profiling the subject's immune response to a viral infection. During this infection, changes in both gene expression and protein profiles related to the insulin response were detected. Just as this subject's personalized medicine profile predicted, he developed diabetes over the course of the two-year study (Figure 10.34). By tracking his iPOP, the onset of diabetes was revealed by the increasing production of RNAs, proteins, and metabolites, such as hemoglobin A1c and lauric acid, related to glucose metabolism (Figure 10.34).

This case study illustrates the potential of iPOPs in monitoring the immune response and disease states. In fact, the omics revolution now allows for genomics, transcriptomics, proteomics, and metabolomics to be performed on different types of immune system cells. The wealth of data from these analyses has led to the development of new immunotherapy options (► Sections 12.8 and 28.4). However, problems such as error rates, the analysis and storage of such large datasets, assessment of complicating factors (such as

additional diseases during the course of the study, Figure 10.34), and ethical issues need to be addressed before iPOPs become routine tools in clinical medicine.

Microbiology as well as biology in general has been forever changed by the genomics age. Our journey through this chapter has only scratched the surface in describing how omics can be used to address previously intractable scientific questions. Much more is almost certainly in store, as major leaps forward in the omics field so far have typically been only one technological advancement away. In Chapter 11 we continue our genomics theme but change our focus from cells to viruses—the most abundant and genetically diverse microbes on Earth.

CHAPTER REVIEW

I • Genomics

- 10.1** Small viruses were the first organisms whose genomes were sequenced, but now many prokaryotic and eukaryotic cellular genomes have been sequenced.

Q What is one discovery resulting from the availability of a microbial genome?

- 10.2** DNA sequencing technology is advancing quickly. These advances have greatly increased the speed of DNA sequencing. Computer analysis of resulting sequencing data is also a vital part of genomics. Computational tools are used not only to annotate genomes but also to analyze sequences and the structures of biological macromolecules.

Q How can protein homology assist in genome annotation?

- 10.3** Sequenced genomes of *Bacteria* and *Archaea* range in size from 0.11 to 16 Mbp. The smallest are smaller than those of the largest viruses, whereas the largest have more genes than some eukaryotes. Gene content in prokaryotic cells is typically proportional to genome size. Many genes can be identified by their sequence similarity to genes found in other organisms. However, a significant percentage of sequenced genes are of unknown function.

Q Approximately how many genes are predicted to be necessary for a microbial cell to have a free-living existence?

- 10.4** Virtually all eukaryotic cells contain mitochondria, and in addition, plant cells contain chloroplasts. Although the genomes of organelles are independent of the nuclear genome, the organelles themselves are not. Many genes in the nucleus encode proteins required for organelle function.

The complete genomic sequence of many microbial eukaryotes has also been determined, and the number of genes ranges from 1000 (less than many bacteria) to 60,000 (more than twice as many as humans).

Q Which genomes are larger, those of chloroplasts or those of mitochondria? How does your genome compare with that of yeast in overall size and gene number?

II • Functional Omics

- 10.5** Once a microbial genome has been sequenced, assembled, and annotated, the role of many genes remains unknown. To characterize new gene products, several functional genomics tools can be applied. These include in particular comparative genome analyses and heterologous gene expression.

Q How can the abundance of available microbial genomes be used to identify new systems that prevent viral infection or horizontal transfer of DNA?

- 10.6** Transposon mutagenesis has been harnessed for identifying gene functions using a high-throughput sequencing methodology. The technique, Tn-Seq, has been used to pinpoint genes in many different bacteria that would be more difficult and laborious to discover using other functional genomic methods.

Q If a gene in *Escherichia coli* was absolutely essential for growth under all conditions, how could you determine this using Tn-Seq?

- 10.7** Most microorganisms in the environment have never been cultured. Nonetheless, analysis of DNA samples has revealed enormous sequence diversity in most habitats. The concept

of the metagenome embraces the total genetic content of all the organisms in a particular habitat.

Q How do the human microbiome and mycobiome differ?

- 10.8** Microarrays consist of oligonucleotide probes corresponding to genes or gene fragments attached to a solid support in a known pattern; mRNA, cDNA, or DNA can then be labeled and hybridized to the gene chip to determine patterns of gene expression or the presence or absence of specific organisms. RNA-Seq combined with sequencing of cDNA can be used to profile the entire transcriptome of an organism.

Q Besides gene expression, what else can be assayed using gene chips?

- 10.9** Proteomics is the analysis of all the proteins present in an organism. The ultimate aim of proteomics is to understand the structure, function, and regulation of these proteins. The interactome is the total set of interactions between macromolecules inside the cell.

Q Besides determining the identity of proteins present under a specific condition, what else can proteomics determine about a microbial proteome?

- 10.10** Metabolomics profiles the complete set of metabolic intermediates produced by an organism. This analysis can determine active metabolic pathways and potential cross-feeding (one organism supplies a nutrient for another organism) in community samples.

Q Why is investigation of the metabolome lagging behind that of the proteome?

III • Systems Biology

- 10.11** With advances in molecular techniques, the genomes of single cells can be sequenced. Expression and protein profiles of single cells can also be determined. These techniques are instrumental for studying as yet uncultured microbes.

Q How can single-cell genomics be used to address microbial dark matter?

- 10.12** By integrating multiple omics datasets in a systems biology approach, computer models predicting molecular activities and interactions in cells can be generated. For example, potential drug targets for the treatment of *Mycobacterium tuberculosis* have been identified using systems biology.

Q How can systems biology be used to discover new diagnostic markers for disease?

- 10.13** Systems biology can also be applied to personal medicine. Besides detecting genetic variants, disease risks can be predicted by profiling a person's genome, transcriptome, proteome, and metabolome.

Q How can omics be used to design immunotherapy strategies?

APPLICATION QUESTIONS

1. Apart from genome size, what factors make complete assembly of a eukaryotic genome more difficult than assembly of a genome from a species of *Bacteria* or *Archaea*?
2. Describe how one might determine which proteins in *Escherichia coli* are repressed when a culture is shifted from a minimal medium (containing only a single carbon source) to a rich medium containing many amino acids, bases, and vitamins. How might one study which genes are expressed during each growth condition?
3. Describe how you could use systems biology to discover a new biologically produced antibiotic.

CHAPTER GLOSSARY

Bioinformatics the use of computational tools to acquire, analyze, store, and access DNA and protein sequences

Codon bias the nonrandom usage of multiple codons encoding the same amino acid; the relative proportions of different codons encoding the same amino acid vary in different organisms. Same as codon usage

Gene chip small, solid supports to which genes or portions of genes are affixed and arrayed spatially in a known pattern (also called microarrays)

Genome the total complement of genes contained in a cell or virus

Genomics the discipline that maps, sequences, analyzes, and compares genomes

Hybridization the joining of two single-stranded nucleic acid molecules by complementary base pairing to form a double-stranded hybrid DNA or DNA–RNA molecule

Interactome the total set of interactions between proteins (or other macromolecules) in an organism

Metabolome the total complement of small molecules and metabolic intermediates of a cell or organism

Metagenome the total genetic complement of all the cells present in a particular environment

Metagenomics the genomic analysis of pooled DNA or RNA from an environmental sample containing organisms that have not been isolated; same as environmental genomics

Microarray small, solid supports to which genes or portions of genes are affixed and arrayed spatially in a known pattern (also called gene chips)

Mobilome the mobile genetic elements in a genome

Nucleic acid probe a strand of nucleic acid that can be labeled and used to hybridize to a complementary molecule from a mixture of other nucleic acids

Open reading frame (ORF) a sequence of DNA or RNA that could be translated to give a polypeptide

Proteome (1) the total set of proteins encoded by a genome or (2) the total protein complement of an organism under a given set of conditions, also called the translome

Proteomics the genome-wide study of the structure, function, and regulation of the proteins of an organism

Sequencing deducing the order of nucleotides in a DNA or RNA molecule by a series of chemical reactions

Systems biology the integration of data from genomics and other “omics” areas to build an overall picture of a biological system

Transcriptome the complement of all RNA produced in an organism under a specific set of conditions

Translatome the total set of proteins produced by an organism under a specific set of conditions

Viral Genomics and Diversity

MICROBIOLOGYNOW

Bacteriophages Mimicking Eukaryotes—Discovery of a Phage-Encoded Nucleus and Spindle

A membrane-bound nucleus is a defining feature of eukaryotic cells that differentiates them from their prokaryotic counterparts. Remarkably, molecular biologists have discovered a group of large *Pseudomonas* bacteriophages whose genomes encode structures resembling the eukaryotic nucleus and mitotic spindle. The obvious question is why, and to understand these remarkable events, scientists needed to understand the roles of both eukaryotic-like structures.

Using fluorescent labeling and cryo-electron microscopy, it was determined that the phage-encoded nucleus contains enzymes specific for replicating and transcribing phage DNA. Once empty phage capsids are assembled at the host membrane, they move rapidly toward the phage nucleus to be filled with phage DNA. The top photo shows a cryo-tomogram slice of a *Pseudomonas chlororaphis* cell infected with the phage 201 ϕ 2-1 (phage virions are about 0.1 μ m in diameter), and the bottom image highlights the following structures in color: nucleus-like structure (blue), capsids (light yellow), phage tails (bright yellow), cytoplasmic and outer membranes (green), and ribosomes (light blue).

I **Viral Genomes and Classification** 362

II **DNA Viruses** 366

III **RNA Viruses** 377

IV **Subviral Agents** 385

How do the capsids move specifically toward the nucleus? The phage-encoded spindle structure (not shown) consists of tubulin filaments that use a treadmill action to advance the empty capsids to the nucleus for DNA packaging. Thus, the phage-encoded nucleus appears to function as a compartment similar to that of eukaryotic viral factories. Once fully assembled, the mature bacteriophages lyse their bacterial host and hunt for new bacterial prey.

Because of the large genomes of the phages that produce these eukaryotic-like structures, it is possible that the events described here increase the efficiency of large bacteriophage multiplication such that they can better compete with smaller bacteriophages that are completely reliant on the host cell machinery for replication. This discovery also begs one of the most fascinating of viral genomics questions: Was the nucleus actually a viral invention?

I • Viral Genomes and Classification

Viruses break several of the molecular rules that govern cells, but perhaps the greatest of these is in the nature of their genomes. In some viral genomes, DNA—the genetic blueprint of cells—is replaced by RNA and the double helix is supplanted by a single strand of nucleic acid.

We learned in Chapter 5 that viruses have either DNA or RNA genomes that can be either single-stranded or double-stranded. Thus, compared with cells, viral genomes can create some unusual challenges for genetic information flow. In this chapter, we take a more detailed look at viral biology. We begin by grouping viruses by their genome structure rather than by the hosts they infect, because viruses with the same genome structure face common problems in genetic information flow. We then consider which viruses infect cells in each of the domains of life and conclude with a discussion of infective agents that are neither cells nor viruses.

11.1 Size and Structure of Viral Genomes

Viral genomes vary almost a thousand-fold in size from smallest to largest and are typically smaller than those of cells. DNA viruses exist along this entire gradient from the tiny circovirus, whose 1.75-kilobase single-stranded genome, which contains three genes, pales in comparison to that of the 2.5-megabase-pair double-stranded DNA genome of *Pandoravirus*, which contains 2500 genes (Figure 11.1). The genome of the latter is over twice that of the previously known largest virus (*Mimivirus*, see Figure 11.5a) and is larger than the genomes of several species of *Bacteria* and *Archaea* (◀ Table 10.1). *Pandoravirus* infects certain marine amoebae, and with virion dimensions of $1\ \mu\text{m} \times 0.5\ \mu\text{m}$, it is also larger than some bacterial cells (Figure 11.1).

RNA virus genomes, whether single- or double-stranded, are typically smaller than DNA viruses and contain 2–40 genes. Although some viral genomes are larger than those of some prokaryotic cells, genomes of *Bacteria* and *Archaea* are typically much larger than those of viruses (Figure 11.1), and genomes of eukaryotes are the largest of all. Viroids, naked infectious RNAs that cause certain plant diseases (Section 11.12), have the smallest genomes of all microbes (Figure 11.1).

Whether a viral genome is large or small, once a virus has infected its host, transcription of viral genes must occur and new copies of the viral genome must be made. Only later, once viral proteins begin to appear from the translation of viral mRNA, can viral assembly begin. For certain RNA viruses, the genome is also the mRNA. For most viruses, however, viral mRNA must first be made by transcription of the DNA or RNA genome, and we now consider the variations on how this occurs.

The Baltimore Scheme: DNA Viruses

The American virologist David Baltimore, who shared with the American Howard Temin and the Italian American Renato Dulbecco the Nobel Prize for Physiology or Medicine in 1975 for the discovery of retroviruses and their key enzyme, reverse transcriptase, developed

Figure 11.1 Comparative genomics. Genome sizes of select viroids, viruses, and archaeal and bacterial cells. Inset: Micrograph of *Pandoravirus*, $\sim 1\ \mu\text{m}$ in length. Bacteriophage phi6 and phage G infect *Pseudomonas* and *Bacillus* species, respectively; other bacterial viruses infect *Escherichia coli*.

a classification scheme for viruses. The scheme is based on the relationship of the viral genome to its mRNA and recognizes seven classes of viruses; three classes have DNA genomes and four have RNA genomes (Figure 11.2). By convention in virology, viral mRNA is always considered to be of the *plus* (+) configuration. Thus, to understand the molecular biology of a particular class of virus, one must know the nature of the viral genome and the steps necessary to produce (+) mRNA from it (Figure 11.2).

Double-stranded DNA viruses are in Baltimore class I. The mechanism of mRNA production and genome replication of class I viruses is the same as that used by cells (Chapter 6). A virus containing a single-stranded genome may be either a **positive-strand** virus (also called a plus-strand virus) or a **negative-strand** virus (also called a minus-strand virus). Class II viruses contain single-stranded plus-strand DNA genomes. Transcription of such a genome would yield (–) mRNA, and thus, before (+) mRNA can be produced from class II viruses, a complementary DNA strand must first be made to form a double-stranded DNA intermediate; this is called the **replicative**

Figure 11.2 The Baltimore classification of viral genomes. Seven classes of viral genomes are known. The genomes can be either (a) DNA or (b) RNA, and either single-stranded (ss) or double-stranded (ds). With the exception of classes V and VI viruses, where the only known examples infect eukaryotic hosts, the top example listed is a bacterial virus and the bottom example an animal virus. The path each viral genome takes to form its mRNA and the strategy each uses for replication is shown.

form. The latter is used to produce (+) mRNA, and as the source of new genome copies, the plus strand becomes the genome while the minus strand is discarded (Figure 11.2). With only one known exception, all single-stranded DNA viruses are positive-strand viruses.

The Baltimore Scheme: RNA Viruses

The production of mRNA and genome replication will obviously be different for RNA viruses than for DNA viruses. Cellular RNA polymerases do not catalyze the formation of RNA from an RNA template, but instead require a DNA template. Therefore, depending on the virus, RNA viruses must either carry in their virions or encode in their genomes an RNA-dependent RNA polymerase called *RNA replicase*. RNA replicases replicate the viral RNA genome and produce viral-specific mRNA. With positive-strand RNA viruses (class IV), the genome is also mRNA. But for negative-strand RNA viruses (class V), RNA replicase must synthesize a plus strand of RNA from the negative-strand template, and the plus strand is then used as mRNA. The plus strand is also used as a template to make more negative-strand genomes (Figure 11.2). RNA viruses of class III face a similar problem but start with double-stranded (+/-) RNA instead of only a positive or negative strand.

Retroviruses are animal viruses whose genomes consist of single-stranded RNA of the plus configuration but replicate through a double-stranded DNA intermediate (class VI). The process of copying the information found in RNA into DNA is called **reverse transcription** and is catalyzed by an enzyme called *reverse transcriptase*. Human immunodeficiency virus (HIV, the causative agent of AIDS) is a retrovirus. Finally, class VII viruses are those highly unusual viruses (human hepatitis B virus is an example) whose

genomes consist of double-stranded DNA but which replicate through an RNA intermediate. As we will see later, these viruses also use reverse transcriptase (Section 11.11).

Hosts for Viruses of Each Baltimore Class

Only certain of the Baltimore classes of viruses are known to infect cells of a particular phylogenetic domain. For example, only two classes are known in *Archaea* and only four in *Bacteria*; only in animals do we find examples of all seven Baltimore classes of viruses (Figure 11.3a). Examples of viruses from each of the Baltimore classes are drawn to scale in Figure 11.3b.

Double-stranded DNA viruses (class I) are the primary viruses infecting prokaryotic cells, while single-stranded plus-sense RNA viruses (class IV) are the major viral predators of eukaryotic cells (Figure 11.3a). As far as is known, fungi are only infected by RNA viruses of classes III and IV, whereas the vast majority of class I viruses that infect eukaryotes replicate in animal hosts rather than plants. By contrast, plants serve as hosts to many more class II viruses than do animals, whereas virtually all class V viruses (viruses with a single-strand minus-sense genome) infect animals rather than plants. And finally, retroviruses (class VI) are known only from animal hosts, while class VII viruses, which like retroviruses depend on reverse transcriptase to replicate their genome, are much more common in plants than in animals (Figure 11.3a). Although the reasons that different genomic classes of virus show specific host preferences is unclear, the fact that *Bacteria* and *Archaea* are hosts for only a relatively small group of viruses suggests that some viral classes may have evolved later in the course of evolution when more complex eukaryotic hosts were available for infection. However,

Figure 11.3 Viral hosts and viral diversity. (a) Virus host preferences by cellular domain (left graph) and in different major groups of eukaryotes (right graph). RT, reverse transcription. Data adapted from Nasir, A., and G. Caetano-Anollés. 2015. *Sci. Adv.* 1: e1500527. (b) Drawings to scale of several viruses discussed in this chapter. The symbols + and - next to viral names indicate the complementarity of the single-stranded DNA or RNA genome of that virus. By convention, all viral mRNAs are designated as + in sequence complementarity.

computational analyses (to be discussed in Chapter 13) suggest that this hypothesis may be incorrect, in that most viral groups, especially the RNA viruses, appear to be of ancient origin.

Viral Protein Synthesis

During the course of viral replication, once (+) mRNA is made (Figure 11.2), viral proteins can be synthesized. In all viruses, these proteins can be grouped into two broad categories: (1) proteins synthesized soon after infection, called *early proteins*, and (2) proteins synthesized later in the infection, called *late proteins*. Both the timing and amount of viral protein synthesis is highly regulated. Early proteins are typically enzymes and are therefore synthesized in relatively small amounts. These include not only nucleic acid polymerases but also proteins that function to shut down host cell transcription and translation. By contrast, late proteins are typically structural components of the virion and other proteins that are not needed until virion assembly begins, and these are made in much larger amounts (◀ Section 5.5).

Virus infection upsets the regulatory mechanisms of the host because there is a marked overproduction of viral nucleic acid and protein in the infected cell. Eventually, when the proper proportions

of viral genome copies and virion structural components have been synthesized, new virions are assembled—typically spontaneously—and exit the host cell by either lysing and killing it or by budding or secretion processes in which the host cell may remain alive.

Check Your Understanding

- Distinguish between a positive-strand RNA virus and a negative-strand RNA virus.
- Contrast mRNA production in the two classes of single-stranded RNA viruses.
- What is unusual about genetic information flow in retroviruses?

11.2 Viral Taxonomy and Phylogeny

Because of the remarkable diversity and abundance of viruses, the Baltimore scheme and host specificity are the easiest way to classify viruses. However, these classifications do not consider relationships between viruses. For example, both rabies and influenza viruses are negative-strand RNA viruses (Baltimore class V), but they possess very different morphology, infection strategies, and genomes. While

we will discuss the evolutionary timeline for viral appearance on Earth and their relationship to cells in Chapter 13, here we focus on taxonomic and phylogenetic relationships between viruses.

Viral Taxonomy

Like microorganisms, viruses can be characterized using a polyphasic approach that includes phenotypic, genotypic, and phylogenetic analyses, or *taxonomy* (► Section 13.12). Within viral taxonomy there are orders, families, subfamilies, genera, and species. The International Committee on Taxonomy of Viruses or ICTV is composed of virologists that oversee the classification and naming of viruses (<http://ictv.global>). ICTV uses a combination of host range, structural morphology, replication cycle, nucleic acid sequence, and pathogenicity to classify viruses. ICTV puts the Baltimore class V rabies and influenza viruses mentioned above in the orders *Mononegavirales* and *Articulavirales*, respectively. Another example of the utility of viral taxonomy is the classification of archaeal viruses. While only two Baltimore classes of viruses have been described to infect *Archaea* (classes I and II; Figure 11.3a), genomic and morphological diversity of these viruses (Section 11.5) places them into 17 different families within unclassified orders.

Figure 11.4 illustrates the distribution of seven major orders of cultured viruses among the three domains of life. While the number of bacteriophages isolated outnumber those of archaeal viruses by a factor of ~20 (Figure 11.3a), 90% of bacteriophages belong to the *Caudovirales* order. Members of the *Caudovirales* are the tailed bacteriophages with double-stranded DNA genomes (Figure 11.3b and Section 11.4). In contrast, only 13% of cultured archaeal viruses belong to this order with over 60% of archaeal viruses belonging to unclassified orders (Figure 11.4). The high number of unclassified archaeal viruses stems from the diverse morphology displayed by those in culture (Section 11.5). Eukaryotic viral classification shares the same diversity issue, with most viruses comprising unclassified orders (Figure 11.4).

Viral Phylogeny

Evolutionary relationships (phylogeny, Chapter 13) among viruses can be difficult to map because they do not possess the ribosomal RNA molecules used to make phylogenetic trees of cells (◀ Section 1.15). Viruses also possess high rates of mutation, especially those with RNA genomes, compared to that of cells. To determine phylogenetic relationships between viruses, the sequences of conserved proteins have been compared along with some structural features. However, in only a few groups of viruses has it been possible to reliably trace phylogenies, and in these cases, trees have been assembled from sequences of a group of genes or proteins shared in common among the group. One such example is *Mimivirus* and its relatives, one of the larger known

Figure 11.4 Taxonomic classification of viruses infecting the three domains of life. The International Committee on Taxonomy of Viruses assignment of viruses into orders based on host. Data adapted from Mahmoudabadi, G., and Phillips, R. 2018. *eLife* 7: e31955.

viruses (Figure 11.5; Chapter 5). *Mimivirus* capsids are multilayered and icosahedral. The virion is surrounded by spikes and is nearly 0.75 μm in diameter (Figure 11.5a), larger than some prokaryotic cells. *Mimivirus* contains a 1.2-megabase double-stranded DNA genome. *Mimivirus* infects the protozoan *Acanthamoeba* and belongs to a group of giant viruses with large genomes called *nucleocytoplasmic large DNA viruses* (NCLDV) (Figure 11.5b). The NCLDV comprise several virus families, including pox viruses (Section 11.6), iridoviruses, and certain plant viruses. These viruses share a set of highly homologous proteins, most of which function in DNA metabolism. A phylogenetic tree of these viruses constructed from DNA sequences encoding these proteins shows how they have diverged from a common ancestor (Figure 11.5b). It is thus possible to track the phylogeny of particular viral groups with some confidence, but to do so, one needs to start with a group that is already known to share a number of properties in common.

Figure 11.5 Phylogeny of nucleocytoplasmic large DNA viruses (NCLDV). (a) Transmission electron micrograph of *Mimivirus*, a member of the NCLDV group. A virion is about 0.75 μm in diameter. (b) Phylogeny of major groups of NCLDV based on comparative sequences of several proteins of DNA metabolism. See Chapter 5 for additional coverage of large viruses.

It is clear that diversity in the viral world is enormous and that obtaining a detailed phylogenetic tree of all viruses will remain a challenge. The continual isolation of highly unusual new viruses makes this difficult task even more challenging. For example, only about 7% of the genes of *Pandoravirus* (Figure 11.1) have gene homologs in existing genomic databases. What this means is that over 90% of the genome of this giant virus will likely be new to biology—a striking example of what awaits discovery in the fascinating world of viruses.

Check Your Understanding

- What type of viruses make up the *Caudovirales* order?
- Lacking ribosomes, how can viruses be placed on the universal tree of life?

II • DNA Viruses

Prokaryotic cells are infected primarily by double-stranded DNA viruses, whereas eukaryotic cells host viruses of all genomic variants. Some DNA viruses are tiny while others are huge, and some DNA animal viruses have novel replication steps or cause tumors in their hosts.

DNA viruses infect a wide variety of organisms, in particular, species of *Bacteria* and *Archaea*. In fact, the majority of viruses that infect prokaryotic cells are DNA viruses, mainly of the double-stranded variety (Figure 11.3). We examine several of these here along with some DNA viruses that infect eukaryotes, and we keep our focus on the genetic information flow that occurs during replication of DNA viruses of different genomic makeups.

11.3 Single-Stranded DNA Bacteriophages: ϕ X174 and M13

In this section we discuss two single-stranded DNA bacteriophages, ϕ X174 and M13. Many single-stranded DNA plant and animal viruses are also known, and because these share with bacterial viruses the fact that their genomes are of the plus complementarity (Baltimore class II, Figure 11.2a), many molecular events are similar. Hence, our focus here will be on the phages.

Bacteriophage ϕ X174

Bacteriophage ϕ X174 contains a circular genome of 5386 nucleotides inside a tiny icosahedral virion, about 25 nm in diameter. Phage ϕ X174 has only a few genes and shows the phenomenon of **overlapping genes**, a condition in which there is insufficient DNA to encode all viral-specific proteins; to overcome this problem, parts of the genome are transcribed in more than one reading frame. For example, in the ϕ X174 genome, gene B resides within gene A, and gene K resides within both genes A and C (Figure 11.6a). Genes D and E also overlap, gene E being contained completely within gene D. Also, the termination codon of gene D overlaps the initiation codon of gene J.

The distinct gene products from overlapping genes are made by reinitiating transcription in a different reading frame within a gene to yield a second (and distinct) transcript. In addition to overlapping genes, a small protein in ϕ X174 called A*, which functions to shut

(a) Genetic map of ϕ X174

(b) Flow of events during ϕ X174 replication

Figure 11.6 Bacteriophage ϕ X174, a single-stranded DNA phage. (a) Genetic map. Note regions of gene overlap. Protein A* is formed using only part of the coding sequence of gene A by reinitiation of translation. The key indicates the functions of the proteins encoded by each gene. Unlabeled parts of the chromosome are regions of noncoding DNA. (b) Genetic information flow in ϕ X174. Progeny single-stranded DNA is produced from the replicative form by rolling circle replication (see Figure 11.7).

down host DNA synthesis, is synthesized by the reinitiation of *translation* (not transcription) within the mRNA for gene A. The A* protein is read from the same mRNA reading frame as the A protein but has a different in-frame start codon and is thus a shorter protein.

As we saw earlier (Section 11.1), before a single-stranded DNA genome can be transcribed, a complementary strand of DNA must be synthesized, forming the double-stranded replicative form. This can then be used as a source of both (+) mRNA and genome copies. Upon infection of an *Escherichia coli* cell by ϕ X174, the viral DNA is separated from the protein coat and the genome is converted into the replicative form by host enzymes. From this, several copies are made by semiconservative replication, and phage-specific transcripts are made by transcription of the negative strand of the replicative

form (Figure 11.6b). The replicative form is also the starting point for making copies of the phage genome by a mechanism called **rolling circle replication** (Figure 11.7). This same mechanism is used by phage lambda, a widely used phage in molecular biology and biotechnology (Section 11.4).

In the synthesis of the ϕ X174 genome, the rolling circle facilitates the continuous production of positive strands from the replicative form. To do this, the positive strand of the replicative form is nicked and the 3' end of the exposed DNA is used to prime synthesis of a new strand (Figure 11.7). Cutting of the plus strand is accomplished by the A protein (Figure 11.6a). Continued rotation of the circle leads to the synthesis of a linear ϕ X174 genome. Note that rolling circle synthesis differs from semiconservative replication (◀ Section 6.3) because only the negative strand serves as a template.

When the growing viral strand reaches unit length (5386 residues for ϕ X174), the A protein cleaves it and then ligates the two ends of the newly synthesized single strand to give a single-stranded DNA circle. Ultimately, assembly of mature ϕ X174 virions occurs and cell lysis follows. The E protein (Figure 11.6a) promotes cell lysis by inhibiting the activity of an enzyme in peptidoglycan synthesis (◀ Section 8.5) in the host cell. Because of the resulting weakness in newly synthesized cell wall material, the host cell ruptures, releasing the phage virions.

Bacteriophage M13

Bacteriophage M13 is a filamentous virus with helical symmetry; the virion is long and thin and attaches to the pilus of its host cell (◀ Figure 5.14). Filamentous phages such as M13 have the unusual property of being released from the host cell without the cell undergoing lysis; infected cells continue to grow, and typical viral plaques (◀ Section 5.3 and Figure 5.10) are not observed. To facilitate the nonlytic release, M13 DNA is covered with coat proteins as it exits across the cell envelope. Four minor coat proteins cover the tips of the virion while the major coat protein covers the sides (Figure 11.8). Thus, mature M13 virions do not accumulate in the cell as occurs

Figure 11.8 Release of phage M13. The virions of phage M13 exit infected cells without lysis. (a) Budding. The virus DNA crosses the cell envelope through a channel constructed from virus-encoded proteins. As this occurs, the DNA is coated with phage proteins that have been embedded in the cytoplasmic membrane. (b) Complete virion. The two ends of the virion are covered with small numbers of the minor coat proteins P3 and P6 (front end) or P7 and P9 (rear end). P8, major coat proteins. Because bacteriophage M13 is a single-stranded DNA phage, it was widely used in the past as a tool for molecular cloning and DNA sequencing (Chapters 10 and 12).

Figure 11.7 Rolling circle replication in phage ϕ X174. Replication begins at the origin of the double-stranded replicative form with the cutting of the plus strand of DNA by gene A protein (both strands of DNA are shown in light green here for simplification). After one new progeny strand has been synthesized (one revolution of the circle), the gene A protein cleaves the new strand and ligates its two ends.

with typical lytic bacteriophages. Instead, these filamentous bacteriophages cause chronic infections.

Several features of phage M13 have made it useful as a cloning and DNA sequencing vehicle in the past. For example, many aspects of DNA replication in M13 are similar to those of ϕ X174 and the genome is very small; this facilitates sequencing efforts. Second, a double-stranded form of genomic DNA essential for cloning purposes is produced naturally when M13 produces its replicative form. Third, as long as infected cells are kept growing, phage can be produced indefinitely, yielding a continuous source of the cloned DNA. These and other features of M13 made this phage a workhorse of the genetic engineering field for many years, although today M13 has been replaced for most genetic engineering tasks by a variety of even more convenient and useful tools, as we will see in Chapter 12.

We transition now from *single-stranded* DNA bacteriophages to *double-stranded* DNA bacteriophages, where, because of the nature of the genome, replication events resemble those in cells but have some unique features as well.

Check Your Understanding

- Why is formation of the replicative form of ϕ X174 necessary in order to make phage-specific mRNA?
- In the ϕ X174 genome, describe the difference between how the gene B and gene A* proteins are made.
- How can M13 virions be released without killing the infected host cell?

11.4 Double-Stranded DNA Bacteriophages: T4, T7, and Lambda

The double-stranded DNA (dsDNA) (Baltimore class I, Figure 11.2a) bacteriophages are among the best studied of all viruses, and we have already discussed two important ones, T4 and lambda, in Chapter 5. Because of their importance in molecular biology, gene regulation, and genomics, we consider details regarding their replication and also that of bacteriophage T7.

Bacteriophage T4

Bacteriophage T4 is a large, tailed, double-stranded DNA virus of *Escherichia coli* that possesses complex morphology (90 nm $\times$ 200 nm; $\blacktriangleleft$ Figure 5.7). As a *virulent* bacteriophage, T4 always kills its host cell following infection ($\blacktriangleleft$ Section 5.5). The T4 genome differs from many other bacteriophage genomes in that its DNA contains the modified cytosine base 5-hydroxymethylcytosine in place of cytosine (Figure 11.9a); this modification is catalyzed by a phage-encoded enzyme and further glycosylated (a glucose molecule is added) to produce a viral nucleotide that cannot be degraded by the cell's restriction modification systems ($\blacktriangleleft$ Sections 5.5 and 9.12).

Because of its large, 170-kilobase-pair linear genome, bacteriophage T4 encodes its own DNA polymerase. Other proteins that function in viral DNA replication

such as primases and helicases ($\blacktriangleleft$ Section 6.3) are also encoded by the T4 genome. In fact, T4 produces its own eight-protein DNA replisome complex ($\blacktriangleleft$ Section 6.4) to facilitate phage-specific genome synthesis. However, the T4 genome does not encode its own RNA polymerase to express these genes. Instead T4-specific proteins modify the specificity of the host RNA polymerase so that it recognizes only phage promoters; these modification proteins are encoded by T4 genes as part of the “early proteins” in the replication cycle ($\blacktriangleleft$ Figure 5.16).

To facilitate expression of only T4-encoded genes, a phage-encoded anti-sigma factor ($\blacktriangleleft$ Section 7.16) is produced that binds to the host RNA polymerase sigma factor and prevents it from recognizing promoters on host genes. This effectively switches the activity of host RNA polymerase from transcribing host-specific genes to transcribing T4-specific genes. Later in the infection process, other phage proteins modify the host RNA polymerase so that it now

Figure 11.9 Circular permutation and the unique DNA of bacteriophage T4. (a) The unique base 5-hydroxymethylcytosine in the DNA of bacteriophage T4. Once this base is glucosylated, the T4 DNA is resistant to restriction enzyme attack. (b) Generation of virus-length T4 DNA molecules with permuted sequences by an endonuclease that cuts off constant lengths of DNA from a concatemer regardless of their sequence.

recognizes T4 promoters of genes encoding middle proteins. Finally, transcription of T4 late genes begins, and this requires a new T4-encoded sigma factor that directs host RNA polymerase to promoters for these genes only. At this point, viral assembly can begin.

Besides encoding an unusual nucleotide and its own replication machinery, the T4 genome has another unusual feature: In a population of T4 virions, although each copy of the genome contains the same set of genes, they are arranged in a different order. This is a phenomenon called *circular permutation*, which is a feature of many virus genomes. The term circular permutation is derived from the fact that DNA molecules that are circularly permuted appear to have been linearized by opening identical circular genomes at different locations. Circularly permuted genomes are also *terminally redundant*, meaning that some DNA sequences are duplicated on both ends of the DNA molecule as a result of the mechanism that generated them.

The T4 genome is first replicated as a unit and then several genomic units are recombined end to end to form a long DNA molecule called a **concatemer** (Figure 11.9b). When the T4 DNA is packaged into capsids, the concatemer is not cut at a specific sequence; instead linear segments of DNA just long enough to fill a phage head are generated. This is called *headful packaging* and is common among bacteriophages. However, because the T4 head holds slightly more than a genome length, the headful mechanism generates terminal repeats of about 3–6 kbp at each end of the DNA molecule (Figure 11.9b).

Bacteriophage T7

Bacteriophage T7 is a relatively small virulent DNA virus that infects *Escherichia coli* and a few related enteric bacteria. The virion has an icosahedral head and a very short tail (Figure 11.3b), and the T7 genome is a linear double-stranded DNA molecule of about 40 kilobase pairs.

When a T7 virion attaches to a host cell and the DNA is injected, early genes are quickly transcribed by host RNA polymerase and then translated. One of these early proteins inhibits the host restriction system, a mechanism for protecting the cell from foreign DNA (◀ Sections 5.5 and 9.12). This occurs very rapidly, as the T7 anti-restriction protein is made and becomes active before the entire T7 genome has entered the cell. Other early proteins include a T7 RNA polymerase and proteins that inhibit host RNA polymerase activity. T7 RNA polymerase recognizes only T7 gene promoters distributed along the T7 genome. This transcriptional strategy differs from that of phage T4 because, as we saw, T4 uses the host RNA polymerase throughout its replication cycle but modifies the host polymerase to recognize only phage genes.

Genome replication in T7 begins at an origin of replication within the molecule and proceeds bidirectionally from this point (Figure 11.10a). Phage T7 uses its own DNA polymerase, which is a composite protein including one polypeptide encoded by the phage

Figure 11.10 Replication of the bacteriophage T7 genome. (a) The linear, double-stranded DNA undergoes bidirectional replication, giving rise to intermediate “eye” and “Y” forms (for simplicity, both template strands are shown in light green and both newly synthesized strands in dark green). (b) Formation of concatemers by joining DNA molecules at their unreplicated terminal ends. (c) Production of mature viral DNA molecules from T7 concatemers by activity of the cutting enzyme, an endonuclease.

and one by the host. As in phage T4, T7 DNA contains terminal repeats at both ends of the molecule and these are eventually used to form concatemers (Figure 11.10b). Continued replication and recombination leads to concatemers of considerable length, but ultimately a phage-encoded endonuclease cuts each concatemer at a specific site, resulting in the formation of linear DNA molecules with terminal repeats that are packaged into phage heads (Figure 11.10c). However, because T7 endonuclease cuts the concatemer at specific sequences, the DNA sequence in each T7 virion is identical. This differs from the situation in phage T4 discussed above, where DNA concatemers are processed using a “headful mechanism” that generates circularly permuted genomes.

Bacteriophage Lambda

Bacteriophage lambda, which also infects *Escherichia coli*, is a double-stranded DNA virus with a head and tail (Figure 11.11a). Lambda is a *temperate* bacteriophage and thus has two possible pathways—lytic or lysogenic. During the lytic cycle, lambda kills its host cells in the same manner as T4 and T7. However, in *lysogeny* lambda differs from T4 and T7 by maintaining a stable relationship with its host. Inside its capsid, the 48.5-kilobase lambda genome is linear and possesses a single-stranded region 12 nucleotides long at the 5' end of each DNA strand. These single-stranded “cohesive” ends are complementary in base sequence; when lambda DNA enters the host cell, they base-pair to form the *cos* site and cyclize (circularize) the genome (Figure 11.11b).

If lambda enters the *lytic* pathway, long, linear concatemers of genomic DNA are synthesized by the rolling circle replication mechanism described for ϕ X174 (Section 11.3). The double-stranded concatemer is then cut into genome-sized lengths at the *cos* sites and the resulting genomes packaged into lambda phage heads (Figure 11.11c). Once the tail has been added and mature lambda virions have been assembled (Figure 11.11a), cell lysis occurs and the virions are released. In its role as a lytic phage, lambda can also package a few chromosomal genes from its lysed host in newly synthesized virions and then transfer these to a second host cell, a process called *transduction*. Transduction is an important means of horizontal gene transfer in nature and is also an important tool in bacterial genetics (Section 9.7).

Instead of the lytic pathway, if lambda takes the *lysogenic* route, its genome integrates into the *E. coli* chromosome. This requires a protein called *lambda integrase*, a phage-encoded enzyme that recognizes the phage and bacterial genome attachment sites (*att* in Figure 11.11b) and facilitates integration of the lambda genome. From this relatively stable state, certain events such as host DNA damage can initiate the lytic cycle once again. After such a trigger, a

Figure 11.11 Bacteriophage lambda: virions, integration of viral DNA and rolling circle replication. (a) Transmission electron micrograph of phage lambda virions. The head of each virion is about 65 nm in diameter and contains linear dsDNA. (b) Lambda DNA integrates at specific attachment (*att*) sites on both the host and phage genomes. Host genes near *att* include *gal*, galactose utilization; *bio*, biotin synthesis; and *moa*, molybdenum cofactor synthesis. Lambda integrase is required, and specific pairing of the complementary ends results in integration of lambda DNA. (c) During rolling circle replication, as one strand (dark green) rolls out, it is both replicated at its opposite end and serves as a template for synthesis of the complementary strand.

lambda excision protein excises the lambda genome from the host chromosome, transcription of lambda DNA begins, and lytic events unfold. With these two contrasting events—lysis and lysogeny—in mind, what controls the path that phage lambda will take?

Lysis or Lysogeny: Regulation of the Lambda Lifestyle

Whether lysis or lysogeny occurs in a lambda infection depends in large part on the levels of two key repressor proteins that can accumulate in the cell following infection: the *lambda repressor*, also called the *cI* protein, and a second repressor called *Cro*. In a nutshell, the first repressor that accumulates will control the outcome of the infection.

If genes encoding the *cI* protein are rapidly transcribed following infection and *cI* accumulates, it represses the transcription of all other lambda-encoded genes, including *Cro*. When this happens, the lambda genome integrates into the host's genome and becomes a prophage (Figure 11.12). The host continues to grow, yielding more lysogens, until an event that triggers lysis is encountered. *Cro*, on the other hand, represses expression of a protein called *cII* whose function is to activate the synthesis of *cI*. Hence, following infection, if *cI* is present at insufficient levels to repress expression of phage-specific genes, *Cro* accumulates in the cell; if this happens, lambda travels the lytic pathway.

Control of these alternative lifestyles—lysis or lysogeny—of lambda has been likened to a “genetic switch,” where a defined series of events must occur for one pathway to be favored over the other. Although infection of an *E. coli* cell by a lambda virion typically results in the lytic cycle, as we have said, lytic events can be switched off if sufficient concentrations of *cII* are present to ensure adequate levels of *cI* (Figure 11.12). But how does this come about? Levels of protein *cII* are controlled by the relative activity of a protease in the cell that slowly degrades *cII* and by levels of yet another

protein, *cIII*, whose function is to stabilize *cII* and protect it from protease attack. We thus have a cascade of regulatory events here: *cIII* controls *cII*, which in turn controls *cI*. But even this is not the end of the story. Several other proteins not described here also play a role in the lambda lytic/lysogenic “decision,” and hence the progress of a lambda infection is a highly intricate series of events.

Indeed, this tiny bacteriophage employs some of the most elaborate regulatory systems known in virology. One of the few lambda proteins expressed during lysogeny prevents the growing lysogen from entering dormancy during stressful conditions (◀ Section 8.12). This regulatory mechanism helps ensure the continued spread of the lambda virus in a mixed population of *Escherichia coli* lysogens and nonlysogens.

Cells of both *Bacteria* and *Archaea* are prokaryotic, and one might predict that what is true for bacterial viruses is also true of archaeal viruses. We see next that this is definitely not the case.

Check Your Understanding

- What is a concatemer?
- How does the mechanism used by bacteriophage T7 to evade the host cell's restriction system differ from that of T4?
- What commits lambda to the lytic versus the lysogenic pathway?

11.5 Viruses of Archaea

Many bacteriophages and archaeal viruses have been isolated and characterized thus far. For *Bacteria*, these include both DNA and RNA phages, some with single-stranded and others with double-stranded genomes. However, all characterized archaeal viruses have DNA genomes, and with rare exception, double-stranded DNA genomes (Figure 11.3a).

DNA Archaeal Viruses

Several DNA viruses have been discovered that infect species in the two main phyla of *Archaea*, the *Euryarchaeota* and the *Crenarchaeota* (Chapter 17). Most viruses that infect species of *Euryarchaeota*, including both methanogenic and halophilic *Archaea*, are of the “head and tail” type, resembling the structurally complex phages that infect enteric bacteria, such as phage T4 (◀ Section 5.5; Section 11.4). Besides two special cases discussed later, all other characterized archaeal DNA viruses contain double-stranded and typically circular DNA genomes.

The most morphologically distinctive archaeal viruses infect hyperthermophilic *Crenarchaeota*. For example, the sulfur chemolithotroph *Sulfolobus* is host to several structurally unusual viruses. One such virus, called SSV, forms spindle-shaped virions that often cluster in rosettes (Figure 11.13a). Such viruses are widespread in acidic hot springs worldwide. Virions of SSV contain a circular DNA genome of about 15 kilobase pairs. A second morphological type of *Sulfolobus* virus forms a rigid, helical rod-shaped structure (Figure 11.13b). Viruses in this class, nicknamed SIFV, contain linear DNA genomes about twice the size of that of SSV. Many variations on the spindle- and rod-shaped patterns have been seen in archaeal viral isolation studies, and a few species of *Crenarchaeota* are also infected by filamentous viruses.

Figure 11.12 Regulation of lytic and lysogenic events in phage lambda. The photomicrographs show time courses of cells of *Escherichia coli* following a course of lytic (left panel, green) or lysogenic (right panel, red) events, as controlled by various repressors. The colors originate from genetically engineered lambda phage that trigger the production of specific fluorescent proteins when either lytic genes (green) or lysogenic genes (red) are expressed. Lytic cells are killed whereas *E. coli* lysogens continue to grow and divide.

Double-stranded DNA viruses

Single-stranded DNA virus

Figure 11.13 Archaeal viruses. Electron micrographs of viruses of *Crenarchaeota* (parts a, b, d, e), and a virus of a euryarchaeote (c). (a) Spindle-shaped virus SSV1 that infects *Sulfolobus solfataricus* (virions are 40×80 nm). (b) Filamentous virus SIFV that infects *S. solfataricus* (virions are 50×900 – 500 nm). (c) Spindle-shaped virus PAV1 that infects *Pyrococcus abyssi* (virions are 80×120 nm). (d) ATV, the virus that infects the hyperthermophile *Acidianus convivor*. When released from the cell the virions are lemon-shaped (left), but they proceed to grow appendages on both ends (right). ATV virions are about 100 nm in diameter. (e) Filamentous virus ACV of *Aerophilum pernix*. ACV virions are about 220 nm long.

A spindle-shaped virus that infects the hyperthermophile *Acidianus* displays a novel behavior. The virion, called ATV, contains a circular genome of about 68 kilobase pairs and is lemon-shaped when first released from the host cells. However, shortly after release from its lysed host cell, the virion produces long, thin tails, one at each end (Figure 11.13d). The tails are actually tubes, and as they form, the virion becomes thinner and its volume is reduced. Remarkably, this is the first example of virus development in the complete absence of host cell contact. It is thought that the extended tails of ATV help the virus in some way survive in its hot (85°C), acidic (pH 1.5) environment or perhaps assist in attachment to a new host cell. This unusually shaped virus is also lysogenic, a property rarely seen in other archaeal viruses.

A spindle-shaped virus also infects the hyperthermophile *Pyrococcus* (*Euryarchaeota*). This virus, named PAV1, resembles SSV but is larger and contains a very short tail (Figure 11.13c). PAV1 has a small circular DNA genome and is released from host cells without cell lysis, probably by a budding mechanism similar to that of the *Escherichia coli* bacteriophage M13 (Section 11.3). *Pyrococcus* has a growth temperature optimum of 100°C and thus PAV1 virions must be extremely heat-stable. Despite their similar morphologies, genomic comparisons of PAV1 and SSV-type viruses show little sequence similarity, indicating that the two types of viruses do not have common evolutionary roots.

Although double-stranded DNA genomes seem to predominate in the *Archaea*, two archaeal viruses have been described that possess single-stranded DNA genomes. Pleomorphic virus 1 (HRPV-1) infects the extreme halophile *Halorubrum* and is unusual not only because of its circular single-stranded DNA genome (of the + complementarity, a property it shares with bacteriophage ϕX174 , Figure 11.6), but also due to its enveloped nonuniform

morphology. Thus, the virus is released by secretion versus the host cell lysis mechanism common to virulent bacteriophage. Over half of the 7048-nucleotide HRPV-1 genome encodes viral proteins that have also been found in the double-stranded DNA haloarchaeal virus His2. This highlights the challenges of classifying viruses based on genome type and the Baltimore scheme (Section 11.1) but also indicates the likely relationships that exist between archaeal viruses of quite different genomic structure. A second archaeal virus possessing a single-stranded DNA genome is the *Aeropyrum* coil-shaped virus (ACV) that infects the hyperthermophile *Aeropyrum pernix* (Figure 11.13e). A filamentous capsid surrounds this circular single-stranded 24.9-kilobase viral genome, which is double the size of the second largest known single-stranded DNA viral genome. Thus, much diversity obviously exists among archaeal viruses.

Genome Content of DNA Archaeal Viruses

While over 2000 bacteriophage genomes have been sequenced, only a little over 100 archaeal viral genome sequences are available in the databases. This disparity in number is due to the difficulty in culturing many archaeal hosts versus their bacterial counterparts. Metagenomic approaches (◀ Section 10.7) are helping expand this number and identify viruses that are not in culture (see discussion of archaeal RNA viruses in next subsection). On average, archaeal virus genomes are smaller than bacteriophage genomes (65 versus 101 open reading frames). Comparative analysis of viral genomes suggests that the genome replication strategies of many archaeal viruses are more similar to those employed by eukaryotic viruses than those used by bacteriophages. Unlike many bacteriophages such as phage T7 (Section 11.4), archaeal viral genomes do not encode a virus-specific RNA polymerase. Thus, archaeal viruses are dependent on the host cell's RNA polymerase

for gene expression, and transcription factors predicted to commandeer the archaeal RNA polymerase have been annotated in many archaeal viral genomes.

Besides the genes for transcription factors mentioned above and some characterized structural proteins, analyses indicate that up to 90% of the genes within many archaeal viral genomes encode proteins of unknown function unrelated to any other proteins in the databases. However, some have been characterized. For example, a unique method of viral release occurs with two archaeal viruses that infect *Sulfolobus islandicus*. Not only do the *S. islandicus* rod-shaped virus 2 (SIRV2) and turreted icosahedral virus (STIV) genomes encode structural proteins for their capsids, they also encode a protein called PVAP (protein forming virus-associated pyramid) that facilitates viral release from the cell. PVAP assembles into seven-fold pyramid structures that rupture the host cell's S-layer (◀ Section 2.5) and open outwards to create a portal for viruses to exit the host cell (Figure 11.14a, b). Heterologous expression (◀ Section 10.5 and Chapter 12) of PVAP in the bacterium *Escherichia coli* also resulted in the formation of pyramid structures that protruded into the periplasmic space (Figure 11.14c), thus indicating that a single archaeal viral protein alone is sufficient for producing these structures. The large number of unique archaeal viral proteins that remain to be characterized will undoubtedly lead to even more remarkable discoveries.

RNA Archaeal Viruses

Thus far, RNA viruses that can replicate in the laboratory on archaeal hosts are unknown, despite the fact that a variety of RNA viruses infect *Bacteria* and eukaryotes (Figure 11.3). Although no concrete examples of archaeal RNA viruses have emerged,

Figure 11.14 Virus-associated pyramids (VAPs). Electron cryotomograph showing a *Sulfolobus islandicus* cell with SIRV2 VAP (a) closed and (b) open. The VAPs open to allow release of virions from the *Sulfolobus* host cell. (c) Transmission electron micrograph showing heterologous expression of the protein for archaeal VAP formation (PVAP) in *Escherichia coli*. The arrows point to pyramid structures formed in the periplasm. The *E. coli* cell is about 0.7 μm in diameter.

Figure 11.15 An acidic Yellowstone hot spring and its archaeal viruses. This spring is a boiling mudpot with a pH of about 2 and is loaded with hyperthermophilic and acidophilic *Crenarchaeota* (▶ Section 17.10). Inset: Transmission electron micrograph of a mixture of archaeal viruses from the spring. Compare with Figure 11.13.

environmental genomics have shown that they almost certainly exist. In some acidic hot springs of Yellowstone National Park (USA) that support large communities of *Crenarchaeota*, a large number of unusually shaped and structurally tough archaeal viruses have been discovered (Figure 11.15) and grown in the laboratory. Thus far, all of these have been DNA viruses. However, using the powerful tools of metagenomics (◀ Section 10.7), researchers studying these hot springs have discovered viral RNAs whose RNA sequences bear no resemblance to those of any known RNA viruses that infect *Bacteria*. Because these springs are too hot for eukaryotes and the cell numbers of *Bacteria* are few, the unusual RNA is almost certainly from RNA archaeal viruses that are yet to be propagated in the laboratory.

Sequence analyses of the hot spring viral RNA show that it originated from single-stranded plus-sense RNA viruses (Baltimore class IV, Figure 11.2b and Section 11.8). These viral genomes also encode an RNA replicase—a hallmark of RNA viruses—and are likely to replicate by way of polyprotein formation, a replication mechanism employed by some class IV viruses of eukaryotes, such as poliovirus (Section 11.8). Replication steps of the putative RNA archaeal viruses, including important molecular details such as the extent to which viral (rather than host) polymerases participate in the replication process, are unclear and await laboratory cultivation of the viruses. However, now that scientists know that such viruses almost certainly exist, they can be on the lookout for them in viral enrichment and isolation studies.

We move on now to consider animal viruses—a group in which there is no shortage of genomic diversity and fascinating replication schemes, many unique to biology.

Check Your Understanding

- What type of genome is seen in most archaeal viruses?
- Compared with other archaeal viruses, what are two unusual features of the virus that infects *Acidianus*?
- Describe the unique mechanism some *Sulfolobus* viruses use to exit the host cell.

11.6 Uniquely Replicating DNA Animal Viruses

Unusual replication strategies are seen in two groups of double-stranded DNA (Baltimore class I, Figure 11.2a) animal viruses: pox viruses and adenoviruses. Pox viruses are unique because all replication events, including DNA replication, occur in the host *cytoplasm* instead of the nucleus, and adenoviruses are unique because the replication of their genome proceeds in a leading fashion on *both* DNA template strands.

Pox Viruses

Pox viruses have been important historically as well as medically. Smallpox virus was the first virus to be studied in any detail and was the first virus for which a vaccine was developed (over 200 years ago the British physician Edward Jenner was the first to protect people from infection by smallpox virus by exposing them to the similar but much less virulent cowpox virus). Pox viruses are among the largest of all viruses, the brick-shaped vaccinia virions measuring almost 400 nm in diameter (Figure 11.16). Because it closely resembles the smallpox virus but is not pathogenic, vaccinia is used as a smallpox vaccine today and as a safe laboratory model for smallpox virus molecular biology.

replication

CDC/PHIL, Fred Murphy and Sylvia Whitfield

Figure 11.16 Smallpox virus. Transmission electron micrograph of a negatively stained thin section of smallpox virus virions. The virions are approximately 350 nm (0.35 μ m) long. The dumbbell-shaped structure inside the virion is the nucleocapsid, which contains the double-stranded DNA genome. All replication functions for pox virus occur in the host cytoplasm.

The vaccinia virus genome consists of linear double-stranded DNA of about 190 kilobase pairs encoding about 250 genes. Following attachment, vaccinia virions are taken up into host cells and the nucleocapsids (Figure 11.16) are liberated in the cytoplasm; all replication events take place in the cytoplasm. Uncoating of the viral genome requires the activity of a viral protein that is synthesized after infection (the gene encoding this protein is transcribed by a viral RNA polymerase contained within the virion). In addition to this uncoating gene, a number of other viral genes are transcribed, including genes that encode a DNA polymerase that synthesizes copies of the viral genome. These are then incorporated into virions that accumulate in the cytoplasm, and the virions are released when the infected cell lyses.

Vaccinia virus has been genetically engineered to contain certain proteins from other viruses for use in *recombinant vaccines* (► Section 12.8). A vaccine is a substance capable of eliciting an immune response in an animal that protects the animal from future infection with the same agent (Chapter 28). Vaccinia virus causes no serious health effects in humans but elicits a strong immune response. Therefore, as a carrier of proteins from pathogenic viruses, vaccinia virus is a relatively safe and effective tool for stimulating an immune response against these pathogens. Success has been obtained with vaccinia virus vaccines against the viruses that cause influenza, rabies, herpes simplex type 1, and hepatitis B. We discuss all of these viruses in upcoming sections.

Adenoviruses

Adenoviruses are a group of small and naked icosahedral viruses (Figure 11.17a) that contain linear double-stranded DNA genomes. Adenoviruses are of minor health importance, causing mild respiratory infections in humans, but they have unique stature in virology because of the mechanism by which they replicate their genomes. Attached to the 5' end of adenoviral genomic DNA is a protein called the adenoviral *terminal protein*, and it is essential for replication of the adenoviral genome. The complementary DNA strands also have inverted terminal repeats that play a role in the replication process (Figure 11.17b).

Following infection, the adenoviral nucleocapsid is released into the host cell nucleus, and transcription of the early genes proceeds by activity of the host RNA polymerase. Most early transcripts encode important replication proteins such as the terminal protein and a viral DNA polymerase. Replication of the adenoviral genome begins at either end of the DNA genome and the terminal protein facilitates this process because it contains a covalently bound cytosine that functions as a primer for DNA polymerase (Figure 11.17b). The products of this initial replication are a completed double-stranded viral genome and a single-stranded minus-sense DNA molecule. At this point, a unique replication event occurs. The single DNA strand cyclizes by means of its inverted terminal repeats, and a complementary (plus-sense) DNA strand is synthesized beginning from its 5' end (Figure 11.17b). This mechanism is unique because double-stranded DNA is replicated *without the formation of a lagging strand*, as occurs in conventional conservative DNA replication (◄ Section 6.3). Once sufficient copies of the adenoviral genome have formed and virion structural components accumulate in the host cell, mature adenoviral virions are assembled and released from the cell following lysis.

CDC/PHIL G. William Gary, Jr.

Figure 11.17 Adenoviruses and their genomic replication. (a) Transmission electron micrograph of adenoviral virions. Note the icosahedral structure. (b) Adenoviral genome replication. Because of loop formation (cyclization), there is no lagging strand; DNA synthesis is leading on both strands. A cytosine (C) is attached to the terminal protein. Adenoviruses are one of several classes of human viruses that cause upper respiratory infections such as the common cold (▶ Section 31.7). Rhinoviruses (single-stranded plus-sense RNA viruses, Section 11.8) cause the vast majority of colds.

In addition to infectious diseases, some animal viruses cause cancer, and we consider these now.

Check Your Understanding

- What is unusual about genome replication in pox viruses?
- What is unusual about genome replication in adenoviruses?
- Why is the adenovirus terminal protein essential for replicating its genome?

11.7 DNA Tumor Viruses

Besides catalyzing lytic events or becoming integrated into a genome in a latent state, some DNA animal viruses can induce the formation of tumors. These include viruses of the polyomavirus family and some herpesviruses, both of which contain double-stranded DNA genomes (Baltimore class I, Figure 11.2a).

Polyomavirus SV40

Polyomavirus SV40 is a naked icosahedral virus that can cause tumors in small mammals, such as hamsters and rats. Its circular genome consists of double-stranded DNA (Figure 11.18a). The genome is too small (5.2 kb) to encode its own DNA polymerase, so host DNA polymerases are used and SV40 DNA is replicated in a bidirectional fashion from a single origin of replication. Because of the small genomes of polyomaviruses, the strategy of overlapping genes, typical of many small bacteriophages (Sections 11.3 and 11.8), is also employed here. Transcription of the viral genome occurs in the nucleus, and the mRNAs are exported to the cytoplasm for protein synthesis. Eventually SV40 virion assembly occurs (in the nucleus) and the cell is lysed to release the new virions.

When SV40 infects a host cell, one of two outcomes can occur, depending on the host cell. In *permissive* hosts, virus infection results in the usual formation of new virions and the lysis of the host cell. In *nonpermissive* hosts, lytic events do not occur; instead, the viral DNA becomes integrated into host DNA, genetically altering the cells in the process (Figure 11.18b). Such cells can show loss of growth inhibition and become malignant, a process called *transformation* (◀ Figure 5.22). As in certain tumor-causing retroviruses (Section 11.11), expression of specific SV40 genes is required to convert the cell to the transformed state. These tumor-inducing proteins bind to and inactivate host cell proteins that control cell division, and in this way, they promote uncontrolled cell development.

Herpesviruses

Herpesviruses are a large group of double-stranded DNA viruses that cause a variety of human diseases, including fever blisters (cold sores), venereal herpes, chicken pox, shingles, and infectious mononucleosis. An important group of herpesviruses cause cancer. For example, Epstein–Barr virus causes Burkitt’s lymphoma, a tumor endemic in children of central Africa and New Guinea. A widespread herpesvirus is *Cytomegalovirus* (CMV), present in nearly three-quarters of all adults in the United States over 40 years of age. For healthy individuals, infection with CMV comes with no apparent symptoms or long-term health consequences. However, CMV can cause

pneumonia, retinitis (an eye condition), and certain gastrointestinal disorders, as well as serious disease or even death in immune-compromised individuals.

Herpesviruses can remain latent in the body for long periods of time and become active under conditions of stress or when the immune system is compromised. Herpesvirus virions are enveloped and can have many distinct structural layers over the icosahedral nucleocapsid (**Figure 11.19**). Following viral attachment, the host cytoplasmic membrane fuses with the virus envelope, and this releases the nucleocapsid into the cell. The nucleocapsid is transported to the nucleus, where the viral DNA is uncoated and three classes of mRNA are produced: *immediate early*, *delayed early*, and *late*

Figure 11.19 Herpesvirus. Flow of events in replication of herpes simplex virus starting from a transmission electron micrograph of herpes simplex virus (diameter of a single virion is about 150 nm). Although the viral genome is linear within the virion, it circularizes once inside the host.

(**Figure 11.19**). Immediate early mRNA encodes certain regulatory proteins that stimulate the synthesis of the delayed early proteins. Among the key proteins synthesized during the delayed early stage is a viral-specific DNA polymerase and a DNA-binding protein, both of which are needed for viral DNA replication. As for other viruses, late proteins are primarily viral structural proteins.

Herpesvirus DNA replication takes place in the nucleus. After infection, the herpesvirus genome circularizes and replicates by a rolling circle mechanism (Section 11.3). Long concatemers are formed that become processed into virus-length genomic DNA during the assembly process (**Figure 11.19**). Viral nucleocapsids are assembled in the nucleus, and the viral envelope is added during budding through the nuclear membrane. Mature herpesvirus virions are subsequently released through the endoplasmic reticulum to the outside of the cell. The assembly of herpesvirus virions thus differs from that of other enveloped viruses, which typically receive their envelope from the cytoplasmic membrane during exit from the cell.

Although we have seen a number of unique genomes and replication schemes with DNA viruses, more is in store with RNA viruses, microbes that cause most common human infectious diseases of viral etiology.

III • RNA Viruses

Viruses that carry an RNA genome cause some of the most notorious diseases of humans and display the most intricate of all viral replication schemes. Because most cellular RNA polymerases are unable to make RNA from an RNA template, RNA viruses carry special enzymes in their virions to accomplish this task.

RNA viruses make up Baltimore classes III–VI (Figure 11.2b) and infect both prokaryotic and eukaryotic cells. As in the foregoing sections that dealt with DNA viruses, we organize our coverage of RNA viruses here by genomic characteristics. We also consider Baltimore class VII viruses, which have a *partially* double-stranded DNA genome, in the final section of this part of the chapter.

11.8 Positive-Strand RNA Viruses

Many viruses contain single-stranded RNA genomes of the plus sense and are therefore *positive-strand RNA viruses*. In these viruses, the sequence of the genome and the mRNA are the same (both are of the + complementarity, Figure 11.2b). A number of positive-strand animal and bacterial viruses are known, so we restrict our coverage here to just a few well-studied cases. We begin with the tiny bacteriophage MS2.

Bacteriophage MS2

Bacteriophage MS2 is about 25 nm in diameter and has an icosahedral capsid. The virus infects cells of *Escherichia coli* by attaching to the cell's pilus (Figure 11.20a), a structure that normally functions in a form of horizontal gene exchange (conjugation) in bacteria (◀ Section 9.8). How MS2 RNA actually gets inside the *E. coli* cell from the pilus is unknown, but once it has, MS2 replication events begin quickly; the genetic map and major activities of this virus are shown in Figure 11.20b and c.

The MS2 genome is just 3.5 kb in size and encodes only four proteins, including the maturation protein, coat protein, lysis protein, and one subunit of **RNA replicase**, the enzyme that replicates the viral RNA (Section 11.1). Interestingly, MS2 RNA replicase is a composite protein, with three subunits encoded by the host genome and one subunit by the viral genome. The gene encoding the MS2 lysis protein overlaps that encoding the coat protein and replicase subunit (Figure 11.20b). We have seen this phenomenon of *overlapping genes* before (Sections 11.3 and 11.7) as a strategy for making small genomes encode more proteins.

(a) Electron micrograph of phage MS2

(b) Genetic map of MS2 RNA genome

(c) Flow of events during viral replication

Figure 11.20 A small RNA bacteriophage, MS2. (a) Transmission electron micrograph of the pilus of a cell of *Escherichia coli* showing virions of phage MS2 attached. (b) Genetic map of MS2. Note how the lysis protein gene overlaps with both the coat protein and replicase genes. The numbers refer to the nucleotide positions on the RNA, the entire genome being 3569 nucleotides in length. (c) Flow of events during MS2 replication.

Because the genome of phage MS2 is plus-sense RNA, it is also the mRNA and is translated directly upon entry into the cell by the host RNA polymerase. When RNA replicase is made, it begins synthesis of minus-sense RNA using plus strands as templates. As minus-sense RNA copies accumulate, more plus-sense RNA is made using the minus-sense strands as templates, and some of these are translated for continued synthesis of viral structural proteins.

Phage MS2 regulates synthesis of its proteins by controlling access of host ribosomes to translational start sites on its RNA. MS2 genomic RNA is folded into a complex secondary structure. Of the four AUG translational start sites (◀ Section 6.9) on the MS2 RNA,

the most accessible to the cell's translation machinery is that for the coat protein and replicase. Hence, translation begins at these sites very early following infection. However, as coat protein molecules accumulate, they bind to the RNA around the AUG start site for the replicase protein, effectively turning off synthesis of replicase. Although the gene for the maturation protein is at the 5' end of the RNA, the extensive folding of the RNA limits access to the maturation protein translational start site, and consequently, only a few copies are synthesized. In this way, all MS2 proteins are made in the relative amounts needed for virus assembly. Ultimately, spontaneous assembly of MS2 virions begins, and the virions are released from the cell as a result of cell lysis.

Poliovirus

Several positive-strand RNA animal viruses cause disease in humans and other animals. These include poliovirus, the rhinoviruses that cause many cases of the common cold, the coronaviruses that cause respiratory syndromes, including severe acute respiratory syndrome (SARS), and the hepatitis A virus. We focus here on poliovirus and coronaviruses, both of which have linear RNA genomes.

Poliovirus is one of the smallest of all viruses with a 30-nm icosahedral structure containing the minimum 60 morphological units (faces) per virion (Figure 11.21a, b). At the 5' terminus of the viral RNA is a protein, called the VPg protein, that is attached covalently to the genomic RNA, and at the 3' terminus is a poly (A) tail (Figure 11.21c), a common feature of eukaryotic cell transcripts (Section 6.6). The poliovirus genome (about 7.4 kb) is also the mRNA, and the VPg protein facilitates binding of the RNA to host

ribosomes. Translation yields a **polyprotein**, a single protein that self-cleaves into several smaller proteins including virion structural proteins. Other proteins generated from the polyprotein include the VPg protein, an RNA replicase responsible for synthesis of both minus-strand and plus-strand RNA, and a virus-encoded protease, which carries out the polyprotein cleavage (Figure 11.21c). This mechanism is called *post-translational cleavage* and is common in many animal viruses as well as animal cells.

Poliovirus replication occurs in the host cell cytoplasm. To initiate infection, the poliovirus virion attaches to a specific receptor on the surface of a sensitive cell and enters the cell. Once inside the cell, the virion is uncoated, and the genomic RNA is attached to ribosomes and translated to yield the polyprotein. Replication of viral RNA by the poliovirus RNA replicase begins shortly after infection. Both the positive and negative strands that are made bind the VPg protein, which also functions as a primer for RNA synthesis following its uridylation (reaction with uridylic acid; Figure 11.21c). Once poliovirus replication begins, host events are inhibited, and about 5 h after infection, cell lysis occurs with the release of new poliovirus virions.

Coronaviruses

Coronaviruses are single-stranded plus RNA viruses that, like poliovirus, replicate in the cytoplasm, but they differ from poliovirus in their larger size and details of replication. Coronaviruses cause respiratory infections in humans and other animals, including about 15% of common colds (Section 31.7 and Figure 32.23b).

Coronavirus virions are enveloped and contain club-shaped glycoprotein spikes on their surfaces (Figure 11.22a). These give the virus

Figure 11.21 Poliovirus. (a) Transmission electron micrograph of poliovirus virions; a single virion is about 30 nm in diameter. (b) A computer model of a poliovirus virion. The various structural proteins are shown in distinct colors. (c) Genomic replication and formation of poliovirus proteins.

the appearance of having a “crown” (*corona* is Latin for crown). Coronavirus genomes are noteworthy because they are the largest of any known RNA viruses, about 30 kb. Because it is of the plus sense, the coronavirus genome can function directly in the cell as mRNA; however, most coronavirus proteins are not made by translating genomic RNA. Instead, only a portion of the genome is translated, in particular the region encoding RNA replicase (Figure 11.22b). The latter then uses the genomic RNA as a template to produce complementary negative strands from which several mRNAs are produced, and these mRNAs are translated to produce coronaviral proteins (Figure 11.22b). Full-length genomic RNA is also made from the negative strands. New coronaviral virions are assembled within the Golgi complex, a major secretory organelle in eukaryotic cells

(Section 2.15), and the fully assembled virions are released later from the cell surface.

Coronavirus differs from poliovirus in terms of virion and genome size, lack of the VPg protein, and absence of polyprotein formation and cleavage. Nevertheless, their single-stranded plus-sense RNA genomes dictate that many other molecular events must occur in a similar way.

In the next two sections we explore some RNA viruses that have genomes unique in the viral world and that cause animal diseases ranging from mild to deadly.

Check Your Understanding

- How can poliovirus RNA be synthesized in the cytoplasm whereas host RNA must be made in the nucleus?
- What is present in the poliovirus polyprotein?
- How are protein synthesis and genomic replication similar or different in poliovirus and coronavirus?

11.9 Negative-Strand RNA Animal Viruses

A number of animal viruses have minus-sense RNA genomes (Baltimore class V, Figures 11.2b and 11.3). In contrast to the plus-strand viruses just considered, the genomes of these negative-strand RNA viruses are *complementary* in base sequence to the mRNA that is formed. We discuss here two important examples of negative-strand RNA viruses: rabies virus and influenza virus. There are no known negative-strand RNA bacteriophages or archaeal viruses.

Rabies Virus

Rabies virus, which causes the fatal neuroinflammatory disease rabies (Section 32.1), is a rhabdovirus, a name that refers to the characteristic shape of the virion (*rhabdos* is Greek for rod). Rhabdoviruses are commonly bullet-shaped (Figure 11.23a) and have an extensive and complex lipid envelope surrounding the helically symmetrical nucleocapsid. A rhabdovirus virion contains several enzymes that are essential for the infection process, including an RNA replicase. Unlike positive-strand viruses, a rhabdovirus genome cannot be directly translated but must first be transcribed by the replicase. This occurs in the cytoplasm and generates two classes of RNAs. The first is a series of mRNAs encoding each of the viral proteins, and the second is a complementary copy of the entire viral genome; the latter functions as a template for the synthesis of genomic RNA copies (Figure 11.23b).

Assembly of a rhabdovirus virion is a highly orchestrated process. Two different coat proteins are made, nucleocapsid and envelope. The nucleocapsid is formed first by assembly of nucleocapsid protein molecules around the viral RNA genome. The envelope proteins are glycoproteins and they migrate to the cytoplasmic membrane where they are inserted into the membrane. Nucleocapsids then migrate to areas on the cytoplasmic membrane where these virus-specific glycoproteins are embedded and bud through them, becoming coated by the glycoprotein-enriched cytoplasmic membrane in the process. The final result is the release of new virions that can infect neighboring cells.

Influenza Virus

Another group of negative-strand RNA viruses contains the important human pathogen *influenza virus*. Influenza virus has been well studied

(a)

(b)

Figure 11.23 Rhabdoviruses. (a) Transmission electron micrograph of vesicular stomatitis virus virions. A virion is about 65 nm in diameter. (b) Flow of events during replication of a negative-strand RNA virus. Note the importance of the viral-encoded RNA replicase.

over many years, beginning with early work during the 1918 influenza pandemic that killed millions of people worldwide (► Sections 30.8 and 31.8). Influenza virus is an enveloped virus in which the viral genome is present in the virion in a number of separate pieces, a condition called a *segmented genome*. In the case of influenza A virus, a common strain, the genome is segmented into eight linear single-stranded molecules ranging in size from 890 to 2341 nucleotides and totaling 13.5 kb. The nucleocapsid of the virus is of helical symmetry, about 6–9 nm in diameter and about 60 nm long, and is embedded in an envelope that has a number of virus-specific proteins as well as lipid derived from the host cytoplasmic membrane. Because of the way influenza virus buds as it leaves the cell, virions do not have a uniform shape and instead are pleomorphic (**Figure 11.24a**).

Several proteins on the outside of the influenza virion envelope interact with the host cell surface. One of these is *hemagglutinin* (Figure 11.24b). Hemagglutinin is highly immunogenic (capable of

(a)

(b)

Figure 11.24 Influenza virus. (a) Transmission electron micrograph of thin sections of human influenza virus virions. (b) Some of the major components of the influenza virus, including the segmented genome.

stimulating the immune system), and antibodies against it prevent the virus from infecting a cell. This is the mechanism by which immunity to influenza is brought about by immunization (► Section 31.8). A second important influenza virus surface protein is the enzyme *neuraminidase* (Figure 11.24b). Neuraminidase breaks down sialic acid (a derivative of neuraminic acid) in the host cytoplasmic membrane. Neuraminidase functions primarily in virus assembly, destroying host membrane sialic acid that would otherwise block assembly or become incorporated into the virion. In addition to hemagglutinin and neuraminidase, influenza virions possess two other key enzymes. These include an RNA replicase, which converts the minus-strand genome into a plus strand, and an RNA endonuclease, which cuts the cap from host mRNAs (◄ Section 6.6) and uses them to cap viral mRNAs so they can be translated by the host translational machinery.

After the influenza virion enters the cell, the nucleocapsid separates from the envelope and migrates to the nucleus. Uncoating activates the virus RNA replicase and transcription begins. Ten proteins are encoded by the eight segments of the influenza virus genome; the mRNAs transcribed from six segments each encode a single protein, while the other two segments encode two proteins each. Some of the viral proteins are needed for influenza virus RNA replication, whereas others are structural proteins of the virion. The overall pattern of genomic RNA synthesis resembles that of the rhabdoviruses (Figure 11.23b), with full-length positive-strand RNA used as a template for making negative-strand genomic RNA. The complete enveloped virion forms by budding, as for the rhabdoviruses.

The segmented genome of the influenza virus has important practical consequences. Influenza virus exhibits a phenomenon called *antigenic shift* in which segments of the RNA genome from two different strains of the virus infecting the same cell are reassorted. This generates hybrid influenza virions that express unique surface proteins unrecognized by the immune system. Antigenic shift is thought to trigger major outbreaks of influenza because immunity to the new forms of the virus is essentially absent from the population. We discuss antigenic shift, and a related phenomenon called *antigenic drift*, in Section 31.8.

Check Your Understanding

- Why is it essential that negative-strand viruses carry an enzyme in their virions?
- What is a segmented genome?
- In influenza virus, what is antigenic shift?

11.10 Double-Stranded RNA Viruses

Viruses with double-stranded RNA genomes (Baltimore class III, Figure 11.2b) infect animals, plants, fungi, and a few bacteria. *Reoviruses* are an important family of animal viruses, and we focus on them here.

Rotavirus is a typical reovirus and is the most common cause of diarrhea in infants 6 to 24 months of age. Other reoviruses cause respiratory infections, and some infect plants. Reovirus virions consist of a nucleocapsid 60–80 nm in diameter, surrounded by a double shell of icosahedral symmetry (Figure 11.25a, b). As we have seen with single-stranded RNA viruses, the virions of double-stranded RNA viruses must carry their own enzyme to synthesize their mRNA and replicate their RNA genomes. Like the influenza virus genome, the reoviral genome is segmented, in this case into 10–12 molecules of linear double-stranded RNA totaling 18 kb.

To initiate infection, a reovirus virion binds to a cellular receptor protein. The attached virus then enters the cell and is transported into lysosomes, where normally it would be destroyed (◀ Section 2.15). However, only the outer coats of the virion are removed by the lysosome, revealing the nucleocapsid; the latter is released into the cytoplasm. This uncoating process activates the viral RNA replicase and initiates virus replication (Figure 11.25c).

Reovirus Replication

Reovirus replication occurs exclusively in the host cytoplasm but *within* the nucleocapsid itself (Figure 11.25c) because the host has enzymes that recognize double-stranded RNA as foreign and would destroy it. The plus strand of the reoviral genome is inactive as mRNA, and thus the first step in replication is the synthesis of plus-sense mRNA by the viral-encoded RNA replicase, using minus-strand RNA as a template; the nucleotide triphosphates necessary for RNA synthesis are supplied by the host (Figure 11.25c). The mRNAs are then capped with a methylated nucleotide (as is typical of eukaryotic mRNAs, ◀ Section 6.6) by viral enzymes and exported from the nucleocapsid into the cytoplasm and translated by host ribosomes.

Most RNAs in the reovirus genome encode a single protein, although in a few cases the protein formed is cleaved to yield the final products. However, one of the reovirus mRNAs encodes two proteins but the

Figure 11.25 The reoviruses. (a) Transmission electron micrograph showing reovirus virions (diameter, about 70 nm). (b) Three-dimensional computer reconstruction of a reovirus virion calculated from electron micrographs of frozen-hydrated virions. (c) The reovirus life cycle. All replication and transcription steps occur inside the nucleocapsids. NTPs, nucleotide triphosphates.

RNA does not have to be processed in order to translate both of these. Instead, a ribosome occasionally “misses” the start codon for the first gene in this mRNA and travels on to the start codon of the second gene to begin translation. When this occurs, the second protein, needed in small amounts, is made but the first protein is not. This “molecular mistake” can be viewed as a primitive form of translational control that ensures that viral proteins are made in their proper amounts.

As viral proteins are formed in the host cytoplasm, they aggregate to form new nucleocapsids, trapping copies of RNA replicase inside as they form (Figure 11.25c). Newly formed nucleocapsids then take up the correct complement of genomic (plus-strand) RNA fragments—probably by recognition of specific sequences on each fragment—and as each single-stranded RNA enters a newly formed

nucleocapsid, a double-stranded form is produced from it by RNA replicase. Once genomic synthesis is complete, viral coat proteins are added in the host's endoplasmic reticulum, and the mature reoviral virions are released by budding or cell lysis (Figure 11.25c).

Reoviruses and RNA Replication

In addition to the unusual genome structure of reoviruses that forces them to employ special mechanisms to protect their double-stranded RNA genomes from cleavage by host ribonucleases (Figure 11.25c), genomic replication in these viruses is also unique and differs in a fundamental way from that of cells and all other viruses.

Because the reovirus RNA genome is double-stranded, one might predict that reovirus replication would parallel that of organisms with double-stranded DNA genomes, but this is not the case. RNA replication in reoviruses is actually a *conservative* process rather than the well-known *semiconservative* process typical of cellular DNA replication and replication in viruses that contain double-stranded DNA genomes (◀ Section 6.3 and Figure 11.2). This is because in the synthesis of reovirus mRNA *only* the minus strand is a template in the infecting nucleocapsids, whereas *only* the plus strand is a template in the synthesis of double-stranded genomic RNA from assimilated plus-strand RNA copies in progeny virions (Figure 11.25c). Hence, in addition to their unique double-stranded RNA genomes, reoviruses also display their unusual molecular biology by employing a unique genomic replication mechanism that is neither semi-conservative nor rolling circle (Figure 11.7) in nature.

Check Your Understanding

- What does the reovirus genome consist of?
- How does reovirus genome replication resemble that of influenza virus, and how does it differ?
- Why must reoviral replication events occur within the nucleocapsid?

11.11 Viruses That Use Reverse Transcriptase

Two different Baltimore classes of viruses use **reverse transcriptase**, an enzyme that can produce DNA from an RNA template, but they differ in the type of nucleic acid in their genomes; retroviruses have RNA genomes while hepadnaviruses have DNA genomes (Baltimore classes VI and VII, respectively, Figure 11.2). Besides their unique molecular properties, both classes of viruses include important human pathogens, including HIV (a retrovirus) and hepatitis B (a hepadnavirus).

Retroviruses and Integration into the Host Genome

Retroviruses have enveloped virions that contain two identical copies of the single-stranded plus complementarity RNA genome (Figure 11.2b and Figure 11.26a). The prefix *retro* means “backward,” and

Figure 11.26 Retrovirus structure and replication. (a) The virion carries two identical copies of the RNA genome (orange). (b) Top, an overview of the infection process. Replication steps: Reverse transcriptase, carried in the virion, makes single-stranded DNA from viral RNA and then double-stranded DNA that integrates into the host genome as a provirus. Transcription and translation of proviral genes leads to the production of new virions that are then released by budding.

the term *retrovirus* refers to the fact that these viruses transfer information from RNA to DNA (in contrast to genetic information flow in cells, which occurs from DNA to RNA). The virion of a retrovirus contains several enzymes, including reverse transcriptase and integrase, and also a specific viral tRNA. Enzymes for retrovirus replication must be carried in the virion because although the retroviral genome is of the plus sense, it is not used directly as mRNA. Figure 11.26*b* illustrates the general scheme for retroviral genome conversion to DNA, integration into the host chromosome, and production of new virions. To begin the process, the genome is converted to DNA by reverse transcriptase inside the nucleocapsid and then the DNA is released to the cytoplasm. The double-stranded DNA is then integrated into the host genome by integrase.

Reverse transcriptase has three enzymatic activities: (1) *reverse transcription* (to synthesize DNA from an RNA template), (2) *ribonuclease activity* (to degrade the RNA strand of an RNA:DNA hybrid), and (3) *DNA polymerase* (to make double-stranded DNA from single-stranded DNA). A more detailed look at steps in reverse transcription is presented in **Figure 11.27**. Reverse transcriptase needs a primer for DNA synthesis and this is the function of the viral tRNA. Using this primer, nucleotides near the 5' terminus of the RNA are reverse-transcribed into DNA. Once reverse transcription reaches the 5' end of the RNA, the process stops. To copy the remaining RNA, a different mechanism comes into play. First, terminally redundant RNA sequences at the 5'

Figure 11.27 Formation of double-stranded DNA from retrovirus single-stranded genomic RNA.

The sequences labeled R on the RNA are direct repeats found at either end. The sequence labeled PB is where the primer (tRNA) binds. Note that DNA synthesis yields longer direct repeats on the DNA than were originally on the RNA. These are called long terminal repeats (LTRs). Inset: A special form of fluorescence microscopy allows visualization of HIV genome integration (green) into a chromosome region near the nuclear membrane (red) of the host cell, a CD4 lymphocyte. Image courtesy of Marina Lusic, University Hospital, Heidelberg, Germany.

end of the molecule are removed by reverse transcriptase. This leads to the formation of a small, single-stranded DNA that is complementary to the RNA segment at the *other end* of the viral RNA. This short, single-stranded piece of DNA then hybridizes with the other end of the viral RNA molecule, where synthesis of DNA begins once again.

Continued reverse transcription leads to the formation of a double-stranded DNA molecule with long terminal repeats, and these assist in integration of the retroviral DNA into the host chromosome by the integrase enzyme carried in the virion (Figure 11.27). For HIV, the chromosomal integration site is not random. Through the use of a special form of fluorescence microscopy, scientists have shown that HIV incorporates into chromosomal loci near the outer shell of the nucleus (photo inset, Figure 11.27). This location is likely favored due to the short life of the viral integrase. Thus the retroviral DNA must be integrated quickly into the host genome upon entry into the nucleus.

Once integrated, retroviral DNA becomes a permanent part of the host chromosome and is considered a *provirus* (◀ Section 5.7); the genes may be expressed or they may remain in a latent state indefinitely. However, if induced, retroviral DNA is transcribed by a cellular RNA polymerase to form RNA transcripts (plus-sense mRNA) that can be either packaged into virions as genomic RNA or translated to yield retroviral proteins.

With retroviruses we thus see a replication scheme that is perhaps the most complex of all known viruses. Despite the complexity of retroviruses, molecular studies of them suggest an ancient origin and possible central importance in the transition from self-replicating RNA life forms to the DNA world of cellular organisms. It is the signature enzyme of retroviruses—reverse transcriptase, the only enzyme known that can make DNA from RNA—that brings retroviruses into this evolutionary limelight, and so it is possible that all cells owe their very existence to this class of viruses. We revisit this topic in Section 13.5.

Hepadnaviruses

In addition to the retroviruses, the second class of unusual viruses that employ the enzyme reverse transcriptase are the **hepadnaviruses**, such as human hepatitis B virus (Figure 11.28a). The tiny DNA genomes of hepadnaviruses are unusual because they are neither single-stranded nor double-stranded; instead, they are *partially* double-stranded. Despite their small size (3–4 kilobase pairs, among the smallest of DNA viruses), the hepadnavirus genomes encode several proteins by containing overlapping genes, a strategy we have seen before in very small viruses (Sections 11.3, 11.7, and 11.8).

In addition to the usual activities of reverse transcriptase we have just considered (Figure 11.27), hepadnaviral reverse transcriptase also functions as a protein primer for synthesis of one of its own DNA strands. In terms of its role in replication events, however, reverse transcriptase plays different roles in retroviral and hepadnaviral genome replication. In hepadnaviruses, the *DNA* genome is replicated through an *RNA* intermediate, whereas in retroviruses, the *RNA* genome is replicated through a *DNA* intermediate (Figures 11.27 and 11.28).

Upon infection, the hepadnavirus nucleocapsid enters the host nucleus where the partial genomic DNA strand is completed by the viral polymerase to form an entire double-stranded molecule. Transcription by host RNA polymerase yields four size classes of viral mRNAs (Figure 11.28b), which are subsequently translated to yield

(a)

(b)

Figure 11.28 Hepadnaviruses. (a) Electron micrograph of hepatitis B virions. (b) Hepatitis B genome. The partially double-stranded genome is shown in the standard green colors. The sizes of the transcripts (orange) are also shown; all of the genes in the hepatitis B virus overlap. Reverse transcriptase produces the DNA genome from a single genome-length mRNA made by host RNA polymerase.

the hepadnaviral proteins. The largest of these transcripts is slightly larger than the viral genome and, together with reverse transcriptase, associates with viral proteins in the host cytoplasm to form genomes for new virions. Reverse transcriptase forms single-stranded DNA from this large transcript inside the virion to form the minus-sense strand of the DNA genome and then uses this DNA as a template to form a portion of the plus-sense strand, yielding the partially double-stranded genome characteristic of hepadnaviruses (Figure 11.28b). Once mature virions are produced, these associate with membranes in the endoplasmic reticulum and Golgi complex, from which they are exported across the cytoplasmic membrane by budding.

Some viral-like microbes are neither viruses nor cells, and we wrap up this chapter by considering their biology.

Check Your Understanding

- Why are protease inhibitors an effective treatment for human AIDS?
- Contrast the genomes of HIV and hepatitis B virus.
- How does the role of reverse transcriptase in the replication cycles of retroviruses and hepadnaviruses differ?

IV • Subviral Agents

A few noncellular microbes are even more streamlined than viruses; some contain RNA but lack protein while others contain protein but lack nucleic acids of any type. Although biologically minimalist entities, these structures can trigger devastating diseases.

We conclude our genomic tour of the viral world by considering two *subviral* agents: the *viroids* and the *prions*. These are infectious agents that resemble viruses but lack either nucleic acid (prions) or protein (viroids) and are thus not viruses.

11.12 Viroids

Viroids are infectious RNA molecules that lack a protein component. Viroids are small, circular, single-stranded RNA molecules that are the smallest known pathogens. They range in size from 246 to 399 nucleotides and show a considerable degree of sequence homology to each other, suggesting that they have common evolutionary roots. Viroids cause a number of important plant diseases and can have a severe agricultural impact (Figure 11.29). A few well-studied viroids include coconut cadang-cadang viroid (246 nucleotides) and potato spindle tuber viroid (359 nucleotides). No viroids are known that infect animals or microorganisms.

Viroid Structure and Function

The extracellular form of a viroid is naked RNA; there is no protein capsid. Although the viroid RNA is a single-stranded, covalently closed circle, its extensive secondary structure forms a hairpin-shaped double-stranded molecule with closed ends (Figure 11.30). This makes the viroid sufficiently stable to exist outside the host cell and protects the viroid while inside the cell from cellular ribonucleases. Because it lacks a capsid, a viroid does not use a receptor to enter the host cell. Instead, the viroid enters a plant cell through a wound, as from insect or other mechanical damage. Once inside,

Figure 11.29 Viroids and plant diseases. Photograph of healthy tomato plant (left) and one infected with potato spindle tuber viroid (PSTV) (right). The host range of most viroids is quite restricted. However, PSTV infects tomatoes as well as potatoes, causing growth stunting, a flat top, and premature plant death.

Figure 11.30 Viroid structure. Viroids consist of single-stranded circular RNA that forms a seemingly double-stranded structure by intra-strand base pairing.

viroids move from cell to cell via plasmodesmata, which are the thin strands of cytoplasm that link plant cells (Figure 11.31).

Viroid RNAs do not encode proteins and thus the viroid is totally dependent on its host for replication. Plants have several RNA polymerases, one of which has RNA replicase activity, and this is the enzyme that replicates the viroid. The replication mechanism itself resembles the rolling circle mechanism used for genome synthesis by some small viruses (Sections 11.3, 11.4, and 11.7). The result is a large RNA molecule containing many viroid units joined end to end. The viroid has ribozyme activity (catalytic RNA, ► Section 13.1) and uses it to self-cleave the large RNA molecule, releasing individual viroids.

Viroid Disease

Viroid-infected plants can be symptomless or show symptoms that range from mild to lethal, depending on the viroid (Figure 11.29). Most disease symptoms are growth related, and it is believed that viroids mimic or in some way interfere with plant small regulatory RNAs. In fact, viroids could themselves be derived from regulatory RNAs that have evolved away from carrying out beneficial roles in the cell to inducing destructive events. Viroids are known to yield small interfering RNAs (siRNAs) as a by-product of replication. It has been proposed that these siRNAs may function by way of an RNA-interference silencing pathway, similar to that of regulatory RNAs in *Bacteria* and *Archaea* (◄ Section 7.12), to suppress the

Figure 11.31 Viroid movement inside plants. After entry into a plant cell, viroids (orange) replicate either in the nucleus or the chloroplast. Viroids can move between plant cells via the plasmodesmata (thin threads of cytoplasm that penetrate the cell walls and connect plant cells). On a larger scale, viroids can also move around the plant via the plant vascular system.

expression of plant genes that show some homology to viroid RNA, and in this way induce disease symptoms. This mechanism of regulation is similar to how some bacterial and archaeal regulatory small RNAs target mRNAs for degradation (◀ Figure 7.28b).

Check Your Understanding

- If viroids are circular molecules, why are they depicted as hairpins?
- How might viroids cause disease in plants?

11.13 Prions

Prions represent the opposite extreme from that of viroids. Prions are infectious agents whose extracellular form consists entirely of protein. That is, *a prion lacks both DNA and RNA*. Prions cause several neurological diseases such as scrapie in sheep, bovine spongiform encephalopathy (BSE or “mad cow disease”) in cattle, chronic wasting disease in deer and elk, and kuru and variant Creutzfeldt–Jakob disease in humans by catalyzing protein conformational changes that lead to protein clumping and accumulation. No prion diseases of plants are known, although prions have been detected in yeast. Collectively, animal prion diseases are known as *transmissible spongiform encephalopathies*.

Prion Proteins and the Prion Infectious Cycle

If prions lack nucleic acid, how is prion protein encoded? The answer to this conundrum is that the host cell itself encodes the prion. The host contains a gene, *Prnp* (Prion protein), which encodes the native form of the prion, known as *PrP^C* (Prion Protein Cellular). This is primarily found in the neurons of healthy animals, especially in the brain (Figure 11.32a). The pathogenic form of the prion protein is designated *PrP^{Sc}* (prion protein Scrapie) because the first prion disease to be discovered was that of scrapie in sheep. *PrP^{Sc}* is identical in amino acid sequence to *PrP^C* from the same animal species, but it has a different conformation. For example, native prion proteins are largely α -helical, whereas the pathogenic forms contain less α -helix and more β -sheet secondary structure. Prion proteins from different species of mammals are similar but not identical in amino acid sequence, and host range is linked in some way to protein sequence. For example, *PrP^{Sc}* from BSE-diseased cattle can infect humans, whereas *PrP^{Sc}* from scrapie-infected sheep apparently cannot.

When the *PrP^{Sc}* form enters a host cell that is expressing *PrP^C*, it promotes the conversion of *PrP^C* into the pathogenic form (Figure 11.32b). That is, the pathogenic prion “replicates” by converting preexisting native prions into the pathogenic form. As the pathogenic prions accumulate and aggregate, they form insoluble crystalline fibers referred to as amyloids in neural cells; this leads to disease symptoms including the destruction of brain and other nervous tissue (Figure 11.32a). *PrP^C* functions in the cell as a cytoplasmic membrane glycoprotein, and it has been shown that membrane attachment of pathogenic prions is necessary before disease symptoms commence. Mutant versions of *PrP^{Sc}* that can no longer attach to nerve cell cytoplasmic membranes still aggregate but no longer cause disease.

Besides the transmissible spongiform encephalopathies, amyloids are also associated with debilitating human diseases such as

CDC/PHIL, Teresa Hammett

(a)

(b)

Figure 11.32 Prions. (a) Section through brain tissue of a human with variant Creutzfeldt–Jakob disease. Note the spongy nature of the tissue (clearings, arrow) where neural tissue has been lost. (b) Mechanism of prion misfolding. Neuronal cells produce the native form of the prion protein. The pathogenic form catalyzes the refolding of native prions into the pathogenic form. The pathogenic form is protease resistant, insoluble, and forms aggregates in neural cells. This eventually leads to destruction of neural tissues (see part a) and neurological symptoms. About 70% of those diagnosed with variant Creutzfeldt–Jakob disease die within a year.

Alzheimer’s, Huntington’s, Parkinson’s, and type 2 diabetes. Whether any or all of these are truly prion diseases is unclear. However, protein aggregation has been linked to these diseases, so the possibility remains that they are manifestations of prion infection.

Nonpathogenic Prions

Certain fungi have proteins that fit the prion definition of an inherited self-perpetuating change in protein structure, although these proteins do not cause noticeable disease. Instead they adapt the fungal cells to survive dynamic environmental conditions by conferring traits such as altered nutrient utilization, antibiotic resistance, and biofilm formation. In yeast, for example, the [URE3] prion is a protein that regulates the transcription of genes encoding certain nitrogen metabolism functions. The normal (soluble) form of this

protein functions to repress genes encoding proteins that metabolize certain nitrogen sources. However, when the [URE3] prion accumulates, it forms insoluble aggregates and when this occurs, the normally repressed genes are derepressed and the nitrogen sources are metabolized.

Humans also have beneficial prions. MAVS is a human protein that is part of our innate immune system and has been shown to convert to a self-perpetuating prion-like form in cells that become infected with a virus. The aggregation of MAVS protein triggers the production of immune modulators called *interferons* (► Section 26.10). These proteins trigger the recruitment of phagocytic cells such as macrophages (cells that ingest and destroy pathogens, foreign particles, and cell debris) and other immune factors to the viral-infected cell, resulting in its destruction. While the conversion of MAVS to a prion-like form ultimately kills the cell, it prevents the virus from hijacking the cell's molecular machinery, which would allow the virus to replicate and lyse the host cell to infect adjacent cells.

The viral and subviral worlds have revealed an almost limitless variation on the molecular principles that govern information flow in cells. We turn our attention in the following chapter to how scientists have exploited some of these unusual molecular principles (along with the enormous repertoire of genetic tools available from cells) to create genetically modified or even totally synthetic organisms for the benefit of mankind.

Check Your Understanding

CHAPTER REVIEW

I • Viral Genomes and Classification

- 11.1** Viral genomes can be single-stranded or double-stranded DNA or RNA and vary from a few to hundreds of kilobases in size. Viral mRNA is always of the plus configuration by definition, but single-stranded genomes can be of the plus or minus configuration. Viruses with RNA genomes must either carry an RNA replicase in their virions or encode this enzyme in their genomes in order to synthesize RNA from an RNA template.

Q Describe the classes of viruses based on their genomic characteristics. For each class, describe how viral mRNA is made and how the viral genome is replicated.

- 11.2** Besides classification based on genomic characteristics, viruses can also be assigned to orders, families, genera, and species based on taxonomy. Taxonomic classifications are made on a combination of host range, structural morphology, replication cycle, nucleic acid sequence, and pathogenicity. Phylogenetic trees illustrating viral relationships can also be constructed using genes conserved within a group of viruses.

Q What trait associated with archaeal viruses is likely responsible for the high percentage of viruses assigned to unclassified orders?

II • DNA Viruses

- 11.3** Single-stranded DNA viruses contain DNA of the plus configuration, and a double-stranded replicative form is necessary for transcription and genome replication. The genome of the virus ϕ X174 is so small that some of its genes overlap, and the genome replicates by a rolling circle mechanism. Some related viruses, such as M13, have

filamentous virions that are released from the host cell without lysis.

Q Describe how the genome of bacteriophage ϕ X174 is transcribed and translated.

- 11.4** Bacteriophage T4 contains a double-stranded DNA genome that is both circularly permuted and terminally redundant. T4 encodes its own DNA polymerase and several other replication proteins, but it utilizes the host RNA polymerase to express early, middle, and late viral genes. Bacteriophage T7 contains a double-stranded DNA genome that encodes both early genes, transcribed by the host RNA polymerase, and late genes, transcribed by a virus-encoded RNA polymerase. Replication of the T7 genome employs T7 DNA polymerase and involves terminal repeats and concatemers. Bacteriophage lambda possesses a linear double-stranded DNA genome that circularizes at the *cos* sites once injected into its host. Depending on cellular conditions, lambda can either integrate into the host chromosome and be maintained as a prophage through lysogeny or enter the lytic cycle and be replicated by rolling circle replication.

Q Why can it be said that transcription of the bacteriophage T4 genome requires one enzyme, while the T7 genome requires two enzymes? How does lambda get incorporated into a host cell's chromosome?

- 11.5** Several double-stranded DNA viruses infect cells of *Archaea*, most of which inhabit extreme environments. Many of these genomes are circular, in contrast to the linear double-stranded DNA genomes of bacteriophages. Although many head-and-tail viruses are known, other archaeal viruses have an unusual spindle-shaped morphology.

Q How is a spindle-shaped double-stranded DNA archaeal virus infecting *Acidianus* capable of surviving in an extremely hot and acidic environment?

- 11.6** Pox viruses are large, double-stranded DNA viruses that replicate entirely in the cytoplasm and are responsible for several human diseases, including smallpox. Adenoviruses are double-stranded DNA viruses whose genome replication employs protein primers and a mechanism that occurs without lagging-strand synthesis.

Q Of all the double-stranded DNA animal viruses, pox viruses stand out concerning one unique aspect of their DNA replication process. What is this unique aspect, and how can this be accomplished without special DNA replication enzymes being packaged in the virion?

- 11.7** Some double-stranded DNA viruses cause cancer in humans. SV40 is such a tumor virus and has a tiny genome containing overlapping genes. The activity of certain SV40 genes can trigger cell transformation (tumor induction). Some herpesviruses also cause cancer, but most cause various human infectious diseases. Herpesviruses can maintain themselves in a latent state in the host indefinitely, initiating viral replication periodically.

Q How does the way herpesviruses obtain their envelope differ from other enveloped viruses?

III • RNA Viruses

- 11.8** In single-stranded plus-sense RNA viruses, the genome is also the mRNA, and a negative strand is synthesized to produce more mRNA and genome copies. The tiny bacteriophage MS2 contains only four genes, one of which encodes a subunit of its RNA replicase. In poliovirus, the viral RNA is translated directly, producing a polyprotein that is cleaved into several small viral proteins. Coronaviruses are large RNA viruses that resemble poliovirus in some but not all of their replication features.

Q What is the function of the VPg protein of poliovirus, and how can coronaviruses replicate without a VPg protein?

- 11.9** In negative-strand viruses, the virus RNA is not mRNA but must first be copied to form mRNA by RNA replicase present in the virion. The positive strand is the template for production of genome copies. Important pathogenic negative-strand viruses include rabies virus and influenza virus.

Q Rabies virus and poliovirus both have single-stranded RNA genomes, but only in poliovirus can the genome be translated directly. Explain.

- 11.10** Reoviruses contain segmented linear double-stranded RNA genomes. Like negative-strand RNA viruses, reoviruses contain an RNA-dependent RNA polymerase within the virion. Newly forming virions take up plus-strand RNA that is the template for the complementary strand produced in the new virions.

Q Compare the reovirus genome to those of influenza virus and bacteriophage MS2. Why do reovirus replication events have to happen in the nucleocapsid?

- 11.11** Some viruses employ reverse transcriptase, including retroviruses (HIV) and hepadnaviruses (hepatitis B). Retroviruses have single-stranded RNA genomes and use reverse transcriptase to make a DNA copy. Hepadnaviruses contain partially double-stranded DNA genomes and use reverse transcriptase to make a single strand of genomic DNA from a full-length complementary strand of RNA.

Q Why do both hepadnaviruses and retroviruses require reverse transcriptase when their genomes are double-stranded DNA and single-stranded RNA, respectively?

IV • Subviral Agents

- 11.12** Viroids are circular single-stranded RNA molecules that do not encode proteins and are dependent on host-encoded enzymes for replication. Unlike viruses, viroid RNA is not enclosed within a capsid, and all known viroids are plant pathogens.

Q What are the similarities and differences between viruses and viroids?

- 11.13** Prions are made of protein but have no nucleic acid of any kind. Prions exist in two conformations, the native cellular form and the pathogenic form, which takes on a different protein structure. The pathogenic form “replicates” itself by converting native prion proteins, encoded by the host cell, into the pathogenic conformation.

Q What are the similarities and differences between prions and viruses?

APPLICATION QUESTIONS

- Not all proteins are made from the RNA genome of bacteriophage MS2 in the same amounts. Can you explain why? One of the proteins functions very much like a repressor, but it functions at the translational level. Which protein is it and how does it function?
- Replication of both strands of DNA in adenoviruses occurs in a continuous (leading) fashion. How can this happen without violating the rule that DNA synthesis always occurs in a 5' → 3' direction?
- Imagine that you are a researcher at a pharmaceutical company charged with developing new drugs against human RNA viral

pathogens. Describe at least two types of drugs you might pursue, what class of virus they would affect, and why you feel that the drugs would not harm the patient.

- Reoviruses contain genomes that are unique in all of biology. Why? Why can't reovirus replication occur in the host cytoplasm? Contrast reovirus genomic replication events with those of a cell. Why can it be said that reovirus genome replication is not semiconservative even though the reovirus genome consists of complementary strands?

CHAPTER GLOSSARY

Concatemer a genomic nucleic acid molecule formed from the recombination of several genomic units

Hepadnavirus a virus whose DNA genome replicates by way of an RNA intermediate

Negative strand a nucleic acid strand that has the opposite sense to (is complementary to) the mRNA

Overlapping genes two or more genes in which part or all of one gene is embedded in another gene

Polyprotein a large protein expressed from a single gene and subsequently cleaved to form several individual proteins

Positive strand a nucleic acid strand that has the same sense as the mRNA

Prion an infectious protein whose extracellular form lacks nucleic acid

Replicative form a double-stranded molecule that is an intermediate in the replication of viruses with single-stranded genomes

Retrovirus a virus whose RNA genome is replicated via a DNA intermediate

Reverse transcriptase the retroviral enzyme that produces DNA from an RNA template

Reverse transcription the process of copying genetic information found in RNA into DNA

RNA replicase an enzyme that can produce RNA from an RNA template

Rolling circle replication a mechanism, used by some plasmids and viruses, of replicating circular DNA, which starts by nicking and unrolling one strand. For a single-stranded genome, this is preceded by using the still-circular strand as a template for DNA synthesis; for a double-stranded genome, the unrolled strand is used as a template for DNA synthesis

Viroid an infectious RNA whose extracellular form lacks protein

MICROBIOLOGYNOW

An Ingestible Biosensor: Using Bacteria to Monitor Gastrointestinal Health

By constantly monitoring and responding to molecules in their environment, microbes possess a remarkable ability to sense and adapt to a range of conditions. Synthetic biologists have exploited this resiliency, along with genetic tractability, to develop microbially driven biosensors for detecting specific stimuli. Now the technology behind these biosensors has been modified to detect markers of human disease.

At the top of the image shown here is a tiny ingestible biosensor that is able to monitor gastrointestinal bleeding (the coin below indicates the scale). The device detects the presence of blood through the response of *Escherichia coli* cells that have been genetically modified to express luminescence genes when exposed to heme, a component released from lysed red blood cells. The square image in the bottom right of the photo shows four quadrants of the device's semipermeable membrane that confines millions of the engineered bacteria. Once loaded with bacteria, the membrane is attached to the capsule such that the bacteria are both

protected and exposed to surrounding molecules as the device travels through the digestive tract.

As the engineered bacteria encounter heme, they modify their gene expression to emit light. Photo transmitters located under the membrane then communicate this response to a microprocessor that ultimately transmits the signal wirelessly to a cell phone. While this biosensor has been successfully used to detect the presence of blood in the stomachs of swine, engineers are working to further miniaturize the electronics. Small as it is, the biosensor's current size (~3.8 cm long) is difficult for humans to swallow.

With current medical procedures for analyzing upper gastrointestinal health requiring expensive and unpleasant procedures, such as endoscopy, the exciting fields of biotechnology and synthetic biology promise future noninvasive and real-time monitoring with as little as a biosensor capsule and a cell phone!

Industrial microbiology uses microbes on a large scale to produce products such as enzymes, foods, and beverages. These microbes are typically not genetically modified. Instead, naturally overproducing strains are selected from wild-type strains and used for industrial purposes. In contrast, biotechnology uses genetically modified microorganisms to produce high-value products that the organisms do not naturally produce. In this chapter we discuss the basic techniques of genetic engineering that underlie biotechnology, in particular those used to clone, alter, and express genes efficiently in host organisms. We also explore how genetic engineering and biotechnology can be used for industrial, medical, and agricultural applications (Figure 12.1) and introduce the exciting new field of **synthetic biology**. The latter is an emerging science that assembles bits and pieces of DNA—aptly called *biobricks*—into entirely new chromosomes or other genetic elements that can modify microbes or even macroorganisms in ways that benefit humans (Figure 12.1).

I • Tools of the Genetic Engineer

DNA from any source can be manipulated in the laboratory in unprecedented ways using the powerful tools of PCR, restriction enzymes, molecular cloning and recombineering, nucleic acid hybridization, and a host of gene expression systems.

Performing genetics *in vivo* (in living organisms) has many limitations that can be overcome by manipulating DNA *in vitro* (in a test tube). **Genetic engineering** refers to the use of *in vitro* techniques to alter genes in the laboratory. Such altered genes may be reinserted into the original source organism or into some other host organism. Expression of a gene from one organism in a different host organism that does not normally possess the gene is called **heterologous expression**.

Genetic engineering requires that specific DNA be isolated, purified, and further manipulated. We begin by considering some of the basic tools of the genetic engineer, including amplification of DNA, the separation of nucleic acids by electrophoresis, nucleic acid hybridization, and molecular cloning. We also describe methods for expressing foreign genes in bacteria and targeted mutagenesis.

12.1 Manipulating DNA: PCR and Nucleic Acid Hybridization

The first objective of genetic engineering is to isolate copies of specific genes in pure form, and the key method for doing so is the **polymerase chain reaction (PCR)** (Figure 12.2). Simply put, the polymerase chain reaction is DNA replication *in vitro*, as segments of target DNA are multiplied by up to a billionfold in the process of *amplification*. During each round of amplification, the amount of DNA *doubles*, leading to an exponential increase in the target DNA. Using an automated PCR machine called a *thermocycler*, a large amount of amplified DNA can be produced from only a few molecules of target DNA. In some cases it is desirable to quantify the initial amount of target DNA, and a variation on PCR called *quantitative PCR (qPCR)* is used for this purpose (► Section 29.8). A second variation on the original PCR technique allows for amplification of RNA (following its conversion to DNA, as discussed later in this section).

PCR and Polymerases

To synthesize DNA, PCR requires DNA polymerase, the enzyme that naturally copies DNA molecules (◀ Section 6.3), and artificially synthesized oligonucleotide primers (Section 12.4) made of DNA (rather than the RNA primers used by cells to replicate DNA). PCR does not actually copy whole DNA molecules but amplifies stretches of up to a few thousand base pairs (the *target*) from within a larger DNA molecule (the *template*) during the following steps (Figure 12.2):

1. Template DNA is heated to denature it (that is, to separate the two strands), and then two DNA oligonucleotide primers complementary to sequences flanking the target DNA on each strand are added in excess. This ensures that most template strands anneal to a primer, and not to each other, as the mixture cools (Figure 12.2a).
2. DNA polymerase then extends the primers using the original DNA as the template (Figure 12.2b).
3. After an appropriate incubation period, the mixture is heated again to separate the strands, but now the target gene is present

Figure 12.1 Genetic engineering and biobrick assembly. Molecular cloning techniques are used to modify organisms for the production of high-value products. RBS, ribosome-binding site; sRNAs, small RNAs; ORFs, open reading frames.

PCR

Figure 12.2 The polymerase chain reaction (PCR). The PCR amplifies specific DNA sequences. (a) Target DNA is heated to separate the strands, and a large excess of two oligonucleotide primers, one complementary to each strand, is added along with DNA polymerase. (b) Following primer annealing, primer extension yields a copy of the original double-stranded DNA. (c) Two additional PCR cycles yield four and eight copies, respectively, of the original DNA sequence. (d) Effect of running 20 PCR cycles on a DNA preparation originally containing 1 copy of a target gene. Note that the plot is semilogarithmic.

in twice the original amount. The mixture is then cooled to allow the primers to hybridize with complementary regions of newly synthesized and original DNA, and the process is repeated (Figure 12.2c). In practice, 20–30 cycles are typically run, yielding a 10^6 -fold to 10^9 -fold increase in the target sequence (Figure 12.2d).

Because high temperatures are used to denature the double-stranded copies of DNA in vitro, use of a thermostable DNA polymerase is critical. *Taq polymerase*, a DNA polymerase isolated from the thermophilic hot spring bacterium *Thermus aquaticus* (► Section 16.20), is stable to 95°C and thus is unaffected by the

denaturation step employed in the PCR (Figure 12.2). A DNA polymerase from *Pyrococcus furiosus*, a hyperthermophilic species of *Archaea* with a growth temperature optimum of 100°C (► Section 17.4), is called *Pfu polymerase* and is even more thermostable than *Taq polymerase*. Moreover, unlike *Taq polymerase*, *Pfu polymerase* has proofreading activity (◄ Section 6.4), making it especially useful when high accuracy is crucial. To supply the demand for thermostable DNA polymerases in biotechnology, the genes encoding these enzymes have been cloned into *Escherichia coli*, allowing the enzymes to be produced commercially in large quantities.

PCR Applications and RT-PCR

PCR is extremely valuable for obtaining DNA for gene cloning or for sequencing purposes because the gene or genes of interest can easily be amplified if flanking sequences are known. PCR is also used routinely in comparative or phylogenetic studies to amplify genes from various sources. In these cases the primers are made commercially to base-pair with regions of the gene that are conserved in sequence across a wide variety of organisms. Because small ribosomal subunit (SSU) rRNA—a molecule used for phylogenetic analyses—has both highly conserved and highly variable regions (► Section 13.11 and Figure 13.24), primers specific for the SSU rRNA gene from different taxonomic groups can be used to survey habitats for their microbial communities (► Section 19.6). Also, because it is so sensitive, PCR can be used to amplify even very small quantities of DNA. For example, PCR has been used to amplify DNA from sources as varied as mummified human remains, fossilized plants and animals, and even single microbial cells (◄ Section 10.11). PCR is also a common tool of medical diagnostics in clinical microbiology laboratories (► Section 29.8) and is widely used in forensic science to link crime scene evidence such as blood, semen, or tissue samples to a specific suspect. In clinical laboratories, especially, time is of the essence, and the faster an infectious disease is diagnosed, the sooner an effective treatment can be chosen and administered.

An important extension of the standard PCR procedure is *reverse transcription PCR* (RT-PCR), used to make DNA from an mRNA template (Figure 12.3). This procedure can be used to detect if a gene is expressed or to produce an intron-free eukaryotic gene for expression in bacteria (Section 12.3). RT-PCR uses the retroviral enzyme *reverse transcriptase* to convert RNA into **complementary DNA (cDNA)** (◄ Sections 11.1 and 11.11). Figure 12.3 illustrates how reverse transcriptase makes a single strand of cDNA using RNA as a template. To make cDNA, a primer complementary to the 3' end of the target RNA is used by the enzyme reverse transcriptase to initiate DNA synthesis. If the template is eukaryotic mRNA, a primer complementary to the poly(A) tail (◄ Section 6.6) of the mRNA can be used. The activity of reverse transcriptase results in a hybrid nucleic acid molecule containing both DNA and RNA. RNase H, a ribonuclease specific for the hybrid molecule, hydrolyzes the RNA, leaving the single-stranded cDNA as template for standard PCR using an additional 5' primer complementary to the 3' end of the cDNA. Note that some commercial reverse transcriptase enzymes used for RT-PCR also possess an RNase H domain.

Figure 12.3 Reverse transcription PCR. Steps in the synthesis of complementary DNA (cDNA) from a eukaryotic mRNA. Reverse transcriptase synthesizes a hybrid molecule containing both RNA and DNA using the mRNA as a template and oligo(dT) primer as a substrate. Next, the enzyme RNase H hydrolyzes the RNA portion of the hybrid molecule, yielding a single-stranded molecule of complementary DNA (cDNA). Following the addition of a 5' primer complementary to the 3' end of the cDNA, Taq polymerase produces a double-stranded cDNA.

Gel Electrophoresis and Nucleic Acid Hybridization

To verify that amplification of a nucleic acid was successful and for other nucleic acid manipulation steps, DNA or RNA fragments can be separated from each other by **gel electrophoresis**, a technique that employs an agarose gel to separate nucleic acid fragments based on differences in their size and charge (Figure 12.4a). When an electrical current is applied, nucleic acids move through the gel toward the positive electrode because of their negatively charged phosphate groups, and small molecules migrate more rapidly than large molecules. After the gel has been run for a time sufficient to separate the molecules, the gel is stained with a dye that binds to nucleic acids and makes them fluoresce, such as *ethidium bromide* (Figure 12.4b). To determine the size of the DNA or RNA of interest, the migration is compared to a standard sample consisting of nucleic acid fragments of known sizes, called a *ladder*. DNA fragments can then be purified from gels and used for a variety of purposes, such as cloning or hybridization.

When DNA is denatured, the single strands can be used to form hybrid double-stranded molecules with other single-stranded DNA (or RNA) molecules by complementary base pairing (◀ Section 6.1) in a process called *nucleic acid hybridization*, or **hybridization** for short. Hybridization is widely used in detecting, characterizing, and

Figure 12.4 Agarose gel electrophoresis of DNA. (a) DNA samples are loaded into wells in a submerged agarose gel. (b) A photograph of a stained agarose gel. The DNA was loaded into wells toward the top of the gel (negative pole) as shown, and the positive electrode is at the bottom. The standard sample in lane A (DNA ladder) has fragments of known size that may be used to determine the sizes of the fragments in the other lanes. Bands stain less intensely at the bottom of the gel because the fragments are smaller, and thus there is less DNA to stain.

identifying segments of DNA and RNA. Single-stranded nucleic acids whose identity is already known and that are used in hybridization are called **nucleic acid probes**, or simply *probes*. To allow detection, probes are made radioactive or are labeled with chemicals that are colored or yield fluorescent products (▶ Section 19.5), and by varying the hybridization conditions, the “stringency” of the hybridization can be adjusted such that complementary base pairing is somewhat flexible or, alternatively, must be nearly exact.

Hybridization is useful for finding related sequences in different genomes or other genetic elements and to determine if a gene is expressed into an RNA transcript. In *Southern blotting*, probes of known sequence are hybridized to target DNA fragments that have been separated by gel electrophoresis. The hybridization procedure in which DNA is the target sequence in the gel, and RNA or DNA is the probe, is called a **Southern blot**. By contrast, a **Northern blot** uses RNA as the target sequence and DNA or RNA as the probe to detect gene expression. In both techniques, the nucleic acid fragments must be in a single-stranded form and are transferred to a synthetic membrane. The membrane is then exposed to the labeled probe. If the probe is complementary to any of the fragments, hybrids form, and the probe attaches to the membrane at the locations of the complementary fragments. Figure 12.5 shows how a Southern blot can be used to identify fragments of DNA containing sequences that hybridize to the probe and how the intensity of a signal on a Northern blot gives a rough estimate of mRNA abundance from the target gene.

Nucleic acid hybridization has many other uses. Hybridization is the basis of the fluorescence in situ hybridization (FISH) technique (▶ Section 19.5) (Figure 12.6), in which fluorescent probes

(a) Southern blot

(b) Northern blot

Figure 12.5 Nucleic acid hybridization. (a) Southern blotting. (Left panel) Purified molecules of DNA from several different plasmids were treated with restriction enzymes and then subjected to agarose gel electrophoresis. (Right panel) Blot of the DNA gel shown to the left. After blotting, DNA in the gel was hybridized to a radioactive probe. The positions of the bands were visualized by X-ray autoradiography. Note that only some of the DNA fragments (circled in yellow in the left panel) have sequences complementary to the labeled probe. Lane 6 contained DNA used as a size marker, and none of its bands hybridized to the probe. (b) Northern blotting. (Top panel) Hybridization and detection of a radioactive gene-specific probe to a blot of total RNA. The probe only bound to RNA from biofilm-grown cells, indicating that the target gene is not expressed during planktonic (suspended) growth. (Bottom panel) Hybridization and detection of a radioactive probe corresponding to the 5S rRNA to the same blot. The signal intensity indicates that equal amounts of RNA from each sample were loaded into the gel.

are used to target specific DNA (or RNA) sequences in cells. This approach allows the identification of pathogens in clinical samples or bacteria of interest in environmental samples. For example, Figure 12.6 demonstrates the simultaneous use of eight different oligonucleotide probes in combinations to distinguish between 28 different strains of *E. coli* whose SSU (small subunit) rRNA sequences varied only slightly from strain to strain. The variations in color give a visual indication of the specificity and power of nucleic acid probes. Hybridization is also important in various “omics,” in particular transcriptomics and metatranscriptomics, where genome-wide gene expression can be monitored in pure cultures and natural populations, respectively, using microarray technology (◀ Section 10.8).

In the next two sections we consider the important processes of gene cloning and the expression of cloned genes, respectively. If either of these events fail, the desired outcome of the genetic engineering will be in doubt.

Figure 12.6 Fluorescence spectral image of 28 differently labeled strains of *Escherichia coli*. Cells were labeled with combinations of fluorophore-conjugated oligonucleotides that are complementary to *E. coli* 16S rRNA. (▶ Figure 13.24).

- How does RT-PCR differ from traditional PCR?
- What are some applications of nucleic acid hybridization in molecular biology?

12.2 Molecular Cloning

The movement of desired genes from their original source to a small and manipulable genetic element (the **vector**) is called **molecular cloning**. Molecular cloning results in **recombinant DNA**, a molecule containing DNA from different sources. Once cloned, the gene(s) of interest can be manipulated, and when the recombinant vector is placed in an appropriate host, the cloned DNA is replicated, providing the foundation for much of genetic engineering.

An Overview of Gene Cloning and Restriction Enzymes

Following isolation of the source DNA, the major steps in gene cloning are (1) inserting the DNA into a cloning vector (Figure 12.7), and (2) inserting the vector into a host. The source DNA can be a gene or genes amplified by the polymerase chain reaction (Section 12.1), DNA synthesized from an RNA template by reverse transcriptase (Section 12.1), or even completely synthetic DNA made in vitro (Section 12.4). Cloning vectors are small, independently replicating genetic elements that can both carry and replicate cloned DNA segments (see Figure 12.10). Cloning vectors are typically designed to allow for easy insertion of foreign DNA. One way to insert foreign DNA into a vector is by using a *restriction site* (Figures 12.7 and 12.8). Restriction endonucleases, or **restriction enzymes** for short, recognize specific base sequences (restriction sites) within DNA and cut the phosphodiester backbone, resulting in double-stranded breaks (Figure 12.8). The recognition sequences—which are unique to each restriction enzyme—are typically inverted repeats and are called *palindromes*.

Figure 12.7 Major steps in gene cloning using restriction enzymes. By cutting the foreign DNA and the vector DNA with the same restriction enzyme, complementary sticky ends are generated that allow foreign DNA to be inserted into the vector.

Restriction enzymes with different sequence specificities are widespread among *Bacteria*, where they help protect cells from attack by viral DNA (◀ Section 9.12). The cell is protected from its own restriction enzyme(s) by chemical modification (typically by methylation) of one of the bases in any potential restriction sites that exist in its genome. The restriction enzyme *EcoRI* makes staggered cuts, leaving short, single-stranded overhangs called “sticky” ends at the termini of the two fragments. Other restriction enzymes such as *EcoRV* cut both strands of the DNA directly opposite each other, resulting in blunt ends (Figure 12.8). If the source DNA and the vector are both cut with the *same* restriction enzyme that yields complementary sticky ends, the two molecules can be joined (annealed) using *DNA ligase*, an enzyme that covalently links the strands of the vector and the source DNA. If the source DNA is PCR generated, *DNA ligase* is used to join the amplified DNA to specialized vectors (see Figure 12.11a, b).

In the final step of gene cloning, recombinant DNA molecules are introduced into suitable host organisms where they can replicate. But in practice, this often yields a mixture of *recombinant* constructs, where only some of the cells contain the desired cloned gene. To identify a host colony containing the correct recombinant DNA, one can select host cells expressing a vector-encoded marker such as antibiotic resistance. Colonies can then be screened for recombinant vectors by looking for the inactivation of a vector gene due to insertion of foreign DNA (see Figures 12.10 and 12.11a, b).

Figure 12.8 Restriction and modification of DNA. Sequences of DNA recognized by the restriction endonucleases *EcoRI* and *EcoRV*. The red arrows indicate the bonds cleaved by the enzyme, and the dashed line indicates the axis of symmetry of the sequence. After cutting DNA with these restriction enzymes, note the single-stranded “sticky” ends generated by *EcoRI* versus the “blunt” ends generated by *EcoRV*.

Recombineering

While cloning with restriction enzymes has been the standard of molecular biology (Figure 12.7), its biggest limitation is that modifications can only be made at restriction enzyme sites. To avoid this requirement, specialized strains of *Escherichia coli* have been designed to allow for gene cloning using homologous recombination (◀ Section 9.5). Through the use of *recombineering* (recombination-mediated genetic engineering), foreign DNA can be inserted into vectors (or the chromosome) by designing the insert DNA to possess short regions (30–50 bases) of sequence homology to the target DNA molecule and activating recombinase enzymes. These recombinase enzymes cleave, exchange, and rejoin strands of DNA between areas of homology. Thus, if the ends of a DNA insert are constructed through PCR to share homology with a vector at the target insertion position, recombinase enzymes will “flip” the DNA insert into the vector (Figure 12.9).

Recombineering was originally developed in the yeast *Saccharomyces cerevisiae*; this microbe, widely used in genetic engineering

Figure 12.9 Recombineering. Enzymes from the lambda Red recombinease system coupled with sequence homology can be used to insert foreign DNA into target sites of vectors and chromosomes. The sequence homology can be generated by PCR and primer design.

(see Figure 12.12), possesses native recombinase enzymes that can recombine DNA regions of sequence homology as short as 20 bases (see Figure 12.40). While homologous recombination does occur naturally in *E. coli*, the efficiency is very low with short regions of homology. Thus, the engineered strains for cloning express the bacteriophage lambda Red recombinase system. The lambda Red (identified from recombination defective phage mutants) system is a mutant form of the system used by the bacteriophage to insert its genome into the *E. coli* chromosome during lysogeny (◀ Section 11.4). The genes encoding this modified recombinase system are located on either a plasmid or the chromosome of the engineered strain, and their transcription is controlled by a repressor protein (Chapter 7) that is sensitive to temperature (Figure 12.9). Thus, the recombinase enzymes are only expressed and active when the temperature is shifted to 40°C. This allows a molecular biologist to control the time point when the recombinases are produced to recombine the foreign DNA in the vector (or chromosome) and helps avoid unwanted recombination events.

Recombineering has revolutionized cloning in *E. coli* because compatible restriction enzyme sites in the vector and the DNA to be cloned are not needed. PCR products or synthesized DNA fragments (Section 12.3) can be recombined into a target site as long as they possess at least 30 base pairs of homology to the desired insertion site. Because the Red recombinase system can also handle single-stranded DNA molecules, oligonucleotide primers can also be synthesized with homology to the target site. Thus, recombineering can be used not only to clone foreign genes into *E. coli*, but also to generate point mutations and gene fusions (see Figure 12.18). After recombineering, recombinant DNA molecules are selected in the same way as gene cloning with restriction enzymes (see Figures 12.10 and 12.11).

Cloning Vectors

Several types of cloning vectors exist, including viruses, cosmids (plasmids with a lambda phage *cos* site, ◀ Figure 11.11), and artificial chromosomes, and their use is dependent on the size of the DNA fragment to be cloned and the host in which the vector will be inserted. Plasmids are widely used cloning vectors that often exist as multiple copies in bacterial cells. The plasmid pUC19 (Figure 12.10) is a standard cloning plasmid that contains an ampicillin resistance gene for selection and a blue–white color-screening system to select for recombinants. It also contains a short segment of artificial DNA containing cut sites for many different restriction enzymes. This segment, called a *multiple cloning site* (MCS), is inserted into the *lacZ* gene encoding the lactose-degrading enzyme β -galactosidase (◀ Section 7.8 and Figure 7.23). The presence of the short MCS does not inactivate *lacZ*, and cut sites for restriction enzymes present in the MCS are absent from the rest of the vector.

The use of pUC19 in gene cloning is shown in Figure 12.10. A suitable restriction enzyme with a cut site within the MCS is chosen, and both the vector and the foreign DNA to be cloned are cut with this enzyme. The vector is linearized, and segments of the foreign DNA are inserted into the open cut site and ligated into position with the enzyme DNA ligase. This insertion disrupts the *lacZ* gene—a phenomenon called *insertional inactivation*—and is used to detect the presence of foreign DNA within the vector or recombinant vector. After DNA ligation, the resulting plasmids are transformed (◀ Section 9.6) into cells of *Escherichia coli* and the cells plated on media containing both ampicillin

Figure 12.10 Cloning into the plasmid vector pUC19. Essential features include an ampicillin resistance marker and the multiple cloning site (MCS) with multiple restriction enzyme cut sites. The cloning vector and foreign DNA are cut with compatible restriction enzymes at positions indicated by the arrows. Insertion of DNA within the MCS inactivates β -galactosidase, allowing blue–white screening for the presence of the insert. The photo on the bottom shows colonies of *Escherichia coli* on an X-gal plate. The enzyme β -galactosidase can cleave the normally colorless X-gal to form a blue product.

(to select for cells containing the plasmid) and a lactose analog called X-gal (5-bromo-4-chloro-3-indolyl- β -D-galactopyranoside), to detect β -galactosidase activity. X-gal, which is colorless, can be cleaved by β -galactosidase to generate a blue product. Thus, cells containing the vector *without* cloned DNA form blue colonies (that is, β -galactosidase is active), whereas cells containing the vector *with* an insert of cloned DNA do not form β -galactosidase and are therefore white and are the focus of further analyses.

Figure 12.11 Specialized vectors. (a) PCR vector with overhangs and *lacZ*. The linearized cloning vector contains overhanging thymidine residues that base-pair with the adenosine residues present on the 3' ends of *Taq*-polymerase-generated PCR. Ligation of the two pieces of DNA yields a circular plasmid containing an interrupted *lacZ* and thus white colonies on plates containing X-gal (see Figure 12.10). (b) PCR vector with blunt ends and *ccdB*. Ligation of a blunt PCR product generated by *Pfu* polymerase yields a circular plasmid containing an interrupted *ccdB*, and thus all

transformants that survive contain a recombinant plasmid. (c) Genetic map of a shuttle vector used in yeast. The vector contains components that allow it to shuttle between *Escherichia coli* and yeast and be selected in each organism: *oriC*, origin of replication in *E. coli*; *oriY*, origin of replication in yeast; *MCS*, multiple cloning site; *ESM*, eukaryotic selectable marker; *CEN*, yeast centromere sequence; *Promoter*; *t/pa*, transcription termination/polyadenylation signals. Ampicillin resistance allows for selection of the vector in *E. coli*. Arrows indicate the direction of transcription. (d) A

yeast artificial chromosome (YAC) containing inserted DNA. The foreign DNA was cloned into the vector at a *NotI* restriction site. The telomeres are labeled *TEL* and the centromere *CEN*. The origin of replication is labeled *ARS* (for autonomous replication sequence). The *URA3* gene is used for selection. The host into which the clone is transformed has a mutation in *URA3* and requires uracil for growth (*Ura⁻*). Host cells containing this YAC become *Ura⁺*. The diagram is not to scale; vector DNA is only 10 kbp whereas cloned DNA can be up to 800 kbp.

Plasmids developed specifically for cloning DNA products synthesized by the polymerase chain reaction (PCR; Section 12.1) have also been designed (Figure 12.11a, b). The enzymatic activity of *Taq* polymerase adds a template-independent adenosine residue to the 3' ends of its products. Linearized vectors are commercially available that contain overhanging thymidine residues that allow for base pairing with the *Taq* PCR product and subsequent ligation using DNA ligase. Ligation of the PCR product results in a circular vector with an interrupted *lacZ* gene for selection of a transformant (Section 9.6) with a recombinant vector (Figure 12.11a).

Because *Pfu* DNA polymerase does not add template-independent adenosine residues, separate linear vectors with blunt ends are available for cloning. These vectors typically rely on insertional inactivation of the *ccdB* gene to select against vectors that rejoin without an insert (Figure 12.11b). CcdB is the toxin component of a toxin-antitoxin module (Section 8.12) that inhibits the enzyme DNA gyrase, and when CcdB is expressed, it prevents DNA replication.

Thus, if the vector is not recombinant, the resulting transformed *E. coli* cells will die from expressing CcdB. This is a strong selection tool because all the resulting colonies from the transformation should contain recombinant vectors (Figure 12.11b).

For manipulating genes in *E. coli* and subsequent cloning into other organisms, **shuttle vectors** are used. These vectors can replicate and be stably maintained in two distinct organisms, such as *E. coli* and yeast or *E. coli* and mammalian cells. The importance of a shuttle vector is that DNA cloned in one organism can be replicated in a second host without having to modify the vector. Thus, the vectors must contain replication, transcription, and selection features for each host, and this is shown for a shuttle vector used in yeast in Figure 12.11c. However, genes can also be cloned directly into the yeast *Saccharomyces cerevisiae* using **yeast artificial chromosomes (YACs)** (Figure 12.11d). YACs are linear vectors that replicate in yeast like normal chromosomes but have sites where very large fragments of DNA can be inserted. To function like

normal eukaryotic chromosomes, YACs have an origin of DNA replication, telomeres for replicating DNA at the ends of the chromosome, and a centromere for segregation during mitosis. YACs also contain a cloning site and a gene for selection following transformation into the host (Figure 12.11d).

Hosts for Cloning Vectors

The most useful hosts for cloning are nonpathogenic microorganisms that are easy to grow and transform with engineered DNA. They must also be genetically stable in culture and have the appropriate enzymes to allow replication of the vector. It is also helpful if considerable background information on the host and a wealth of tools for its genetic manipulation exist. Hosts that meet these conditions include the bacteria *E. coli* and *Bacillus subtilis*, and the yeast *S. cerevisiae* (Figure 12.12). Complete genome sequences are available for all of these organisms, and they are widely used as cloning hosts.

Although *E. coli* is found in the human intestine and some wild-type strains are potentially harmful (► Section 33.11), several modified *E. coli* strains have been developed specifically for cloning purposes. However, if cloned gene *expression* is desired, the outer membrane of this gram-negative bacterium (◄ Section 2.4) can hinder protein secretion. This problem can be overcome using the gram-positive bacterium *B. subtilis* as a cloning host (Figure 12.12). Cloning of DNA from eukaryotic sources into eukaryotic rather than prokaryotic cells is often done since eukaryotic hosts already possess the complex RNA and post-translational processing systems required for the production of eukaryotic proteins (◄ Section 6.6). Because it is easy to grow and manipulate, the workhorse for cloning in eukaryotic cells is the yeast *S. cerevisiae*. However, some cloning applications require the use of plant tissues, insect cell lines, or cultured mammalian cells. Regardless of host type, it is necessary to get cloned DNA into the host. While chemical transformation and electroporation (◄ Section 9.6) are often used to introduce DNA into cells of *Bacteria* and *Archaea*, methods such as transfection (see Figure 12.21), microinjection, and electroporation can be used for eukaryotic cells.

Bacteria		Eukaryote
<i>Escherichia coli</i>	<i>Bacillus subtilis</i>	<i>Saccharomyces cerevisiae</i>
		
Well-developed genetics Many strains available Most-studied bacterium	Easily transformed Nonpathogenic Naturally secretes proteins Endospore formation simplifies culture	Well-developed genetics Nonpathogenic Can process eukaryotic mRNAs Easy to grow
Potentially pathogenic Periplasm traps proteins	Genetically unstable Genetics less developed than in <i>E. coli</i>	Plasmids unstable Will not replicate most bacterial plasmids
Advantages		Disadvantages

12.3 Expressing Foreign Genes in *Bacteria*

Once genes are cloned, they can be transcribed and translated (expressed) to produce their encoded proteins. Obstacles to the expression of genes from mammalian or other eukaryotic sources in bacteria include the following: (1) The genes must be placed under control of a bacterial promoter; (2) any introns (◄ Section 6.6) must be removed; (3) codon usage (codon bias, ◄ Section 6.9) may require edits to gene sequences; and (4) many eukaryotic proteins require host modification after translation to yield the active form and bacteria cannot perform most such modifications. Here we consider solutions to these challenges.

Transcription and Translation of Cloned Genes Using Expression Vectors

Expression vectors are designed to allow the experimenter to control the expression of cloned genes. However, the native promoter of a cloned gene may work poorly in a new host, and the overproduction of foreign proteins may also damage the host cell. Therefore, it is important to regulate the expression of cloned genes. Typically, the regulation is at the transcriptional level, and in practice, high levels of transcription require strong promoters that bind RNA polymerase efficiently (◄ Section 6.5). An example of this is the use of the bacteriophage T7 promoter and T7 RNA polymerase to regulate gene expression. When T7 infects *Escherichia coli*, it encodes its own RNA polymerase that recognizes only T7 promoters (◄ Section 11.4). In T7 expression vectors, cloned genes are placed under control of the T7 promoter. To achieve this, the gene for T7 RNA polymerase must also be present in the cell under the control of an easily regulated system, such as *lac* (◄ Section 7.3; Figure 12.13). This is usually done by integrating the gene for T7 RNA polymerase with a *lac* promoter into the chromosome of a specialized host strain.

The BL21 series of *E. coli* host strains are especially designed to work with the pET series of T7 expression vectors (Figure 12.13). The cloned genes are expressed shortly after T7 RNA polymerase transcription has been switched on by a *lac* inducer, such as the chemical IPTG (◄ Section 7.3). Because it recognizes only T7 promoters, the T7 RNA polymerase transcribes only the cloned genes. The T7 RNA polymerase is so highly active that it uses most of the RNA precursors, thereby limiting transcription to the cloned genes. Consequently, host genes that require host RNA polymerase are for the most part not transcribed and thus the cells stop growing; translation in such cells then yields primarily the protein of interest. The T7 control system is thus very effective for generating large amounts of a specific protein.

Expression vectors must also be designed to ensure that the mRNA produced is efficiently translated. To synthesize protein from an mRNA molecule, it is essential for the ribosomes to bind at the correct site and begin reading in the correct frame. In bacteria this is

Figure 12.13 The T7 expression system. The gene for T7 RNA polymerase is in a gene fusion under control of the *lac* promoter and is inserted into the chromosome of a special host strain of *Escherichia coli* (BL21). Addition of IPTG induces the *lac* promoter, causing expression of T7 RNA polymerase. This transcribes the cloned gene, which is under control of the T7 promoter and is carried by the pET plasmid. RBS, ribosome-binding site.

accomplished by having a ribosome-binding site (RBS, ◀ Section 6.9) and a nearby start codon on the mRNA. Bacterial RBSs are not found in eukaryotic genes and must be engineered into the vector if high levels of expression of the eukaryotic gene are to be obtained.

Other adjustments to a cloned gene may be necessary to ensure high-efficiency translation. For example, *codon usage* can be an obstacle. Codon usage is related to the concentration of the appropriate tRNA in the cell (◀ Section 10.2 and Table 10.3). Because of the redundancy of the genetic code, more than one tRNA exists for most amino acids (◀ Section 6.9). Therefore, if a cloned gene has a codon usage pattern distinct from that of its expression host, it will probably be translated inefficiently in that host. Site-directed mutagenesis (Section 12.4) can be used to change selected codons in the gene, making it more amenable to the codon usage pattern of the host.

Cloning the Gene via mRNA or Artificial Synthesis

If a cloned gene contains introns, as eukaryotic genes typically do (◀ Section 6.6), the correct protein product will not be made in a bacterial host unless modifications are made. This can be done via mRNA. In a typical mammalian cell, less than 5% of the total RNA is mRNA. However, eukaryotic mRNA is unique because of the poly(A) tails found at the 3' end (◀ Section 6.6), and this makes it easy to isolate, even though it is of low abundance. If a cell extract is passed over a chromatographic column containing strands of poly(T) linked to a cellulose support, most of the mRNA separates from other RNAs by sticking to the support by specific pairing of As and Ts. The RNA is then released from the column by a low-salt buffer, which gives a preparation greatly enriched in mRNA.

Once mRNA has been isolated, the genetic information is converted into complementary DNA (cDNA) by RT-PCR as was illustrated in Figure 12.3. This double-stranded cDNA contains the coding sequence but lacks introns (Figure 12.14), and thus it can be

Figure 12.14 Complementary DNA (cDNA). Steps illustrating the synthesis of an intron-lacking cDNA corresponding to a eukaryotic gene generated by reverse transcription PCR (RT-PCR; see Figure 12.3).

inserted into a plasmid or other vector for cloning in bacteria. However, because the cDNA contains only coding sequences, it lacks a promoter and other upstream regulatory sequences necessary for expression. Thus expression vectors containing bacterial promoters and ribosome-binding sites (RBS) are used to obtain high-level expression of genes cloned in this way (see Figure 12.15).

For small proteins it is possible to artificially synthesize the entire gene (Section 12.4). Many mammalian proteins such as high-value peptide hormones are made by protease cleavage of large precursor molecules. Thus, in order to produce a short peptide such as insulin in its active form, construction and cloning of an artificial gene that encodes just the final hormone rather than the larger precursor protein from which it was derived may have several advantages. Constructed genes are naturally free of introns and thus the mRNA does not need processing. Also, promoters and other regulatory sequences can be inserted into the gene upstream of the coding sequences, and codon bias (◀ Sections 6.9 and 10.2) can be adjusted to best suit the expression host.

Protein Stability and Purification

The synthesis of a protein in a new host may spawn additional problems. For example, some proteins are susceptible to degradation by protease enzymes and others may be toxic to their host. Also, when proteins are massively overproduced, they sometimes aggregate into insoluble inclusions. Although inclusions are relatively easy to purify, the protein they contain is often difficult to solubilize and may be partially denatured. Protein purification can be simplified if the target protein is made as a *fusion protein* along with a carrier protein encoded by the vector. To do this, the

two genes are fused to yield a single coding sequence. A short segment that is recognized and cleaved by a commercially available protease is included between them. After transcription and translation, a single protein is made that is purified by methods designed for the carrier protein. The fusion protein is then cleaved by the protease to release the target protein from the carrier protein. Fusion proteins simplify purification of the target protein because a carrier protein is chosen that will not form inclusions and is easy to purify.

Several vectors are available to generate fusion proteins, and **Figure 12.15** shows an example of a fusion vector that is also an expression vector. In this example, the carrier protein is the *E. coli* maltose-binding protein (encoded by *malE*, **Figure 12.15**), a protein that is easily purified by methods based on its high affinity for maltose. Once purified, the two portions of the fusion protein are separated by protease or chemical treatment. One other advantage of making a fusion protein is that the carrier protein can be chosen to contain the bacterial *signal sequence*, a peptide rich in hydrophobic amino acids that enables transport of the protein across the cytoplasmic membrane (◀ **Section 6.12**). This makes possible a bacterial expression system that not only *makes* and *secretes* mammalian proteins, but also allows for the heterologously expressed protein to be separated from all of the other proteins secreted by the cell using binding resins specific for the maltose-binding protein. Thus, carrier proteins can be used to save time, money, and effort in obtaining a desired product.

In the next two sections we will see how some of the DNA manipulations we have already considered can be used to generate mutants of interest and how some genes can be exploited as signals of gene expression.

Figure 12.15 An expression vector for gene fusions. The gene to be cloned is inserted into the multiple cloning site (MCS) to be in frame with the *malE* gene, which encodes maltose-binding protein. The insertion inactivates the gene for the alpha fragment of *lacZ*, which encodes β -galactosidase. The fused gene is under control of the hybrid *tac* promoter (*P_{tac}*) and an *Escherichia coli* ribosome-binding site (RBS). The plasmid also contains the *lacI* gene, which encodes the *lac* repressor. Therefore, an inducer must be added to turn on the *tac* promoter. The plasmid contains a gene conferring ampicillin resistance on its host.

- What major advantage does cloning mammalian genes from mRNA or using synthetic genes have over PCR amplification and cloning of the native gene?
- How is a fusion protein made?

12.4 Molecular Methods for Mutagenesis

Conventional mutagens introduce mutations *at random* in the DNA of the intact organism (◀ **Section 9.4**). In contrast, **site-directed mutagenesis** uses synthetic DNA plus DNA cloning techniques to introduce mutations into genes *at precisely determined sites*. In addition to changing one or just a few bases, mutations may also be engineered by inserting large segments of DNA at precisely determined locations.

Site-Directed Mutagenesis

Site-directed mutagenesis is now a fairly straightforward process due to the ease in obtaining 12- to 40-base DNA oligonucleotides of precise sequence through chemical synthesis; primers or probes for use in the polymerase chain reaction (PCR) and hybridization are obtained in the same manner (**Section 12.1**). In fact, DNA oligonucleotides over 100 bases long can be obtained. Thus, PCR can be used to obtain a gene with a specific mutation depending on the position of the desired change. If the target gene is part of the *Escherichia coli* chromosome or has already been cloned into a vector, a PCR product (or even an oligonucleotide) containing the desired mutation can be exchanged through recombineering using an appropriate strain of *E. coli* (**Figure 12.9** and **Figure 12.16a**). This scheme allows any base pair in a specific gene to be changed. Progeny bacteria are then screened through PCR and subsequent Sanger sequencing of the product to detect those carrying the mutation (◀ **Figure 10.4**). When the mutated gene is expressed, a protein with an altered amino acid sequence will be produced. Site-directed mutagenesis can thus be used to manipulate proteins to test the functional importance of specific amino acids at specific sites in the protein.

Site-directed mutagenesis has many applications. The technique has been widely used by enzymologists to change a specific amino acid in the active site of an enzyme to see how the modified enzyme compares with the wild-type enzyme. In such experiments, the vector encoding the mutant enzyme is inserted into a mutant host strain unable to make the original enzyme. Consequently, the activity measured is due to the mutant version of the enzyme alone. Using *in vitro* mutagenesis, enzymologists can link virtually any aspect of an enzyme's activity—catalysis, resistance, susceptibility to chemical or physical agents, interactions with other proteins—to specific amino acids in the enzyme. In genetic engineering, site-directed mutagenesis has been used to improve the properties of specific proteins, and we discuss some examples in **Section 12.6**.

Cassette Mutagenesis and Gene Disruption

To make more than a few base-pair changes or replace entire sections of a gene of interest, synthetic fragments called **DNA cassettes** (or cartridges) can be used to mutate DNA in a process known as

Figure 12.16 Site-directed mutagenesis and gene disruption by cassette mutagenesis. (a) Site-directed mutagenesis. A short stretch of DNA containing a single base change is inserted into a target gene such that the target gene product is altered in a known way at a known position in the polypeptide. (b) Gene disruption by a cassette insertion. (1) A cloned wild-type copy of gene X, carried on a plasmid, and a kanamycin cassette are cut with *EcoRI*, mixed, and ligated. (2) The resulting plasmid contains the kanamycin cassette as an insertion mutation within gene X. This new plasmid is cut with *BamHI* and transformed into a cell. (3) The transformed cell contains the linearized plasmid with a disrupted gene X and its own chromosome with a wild-type copy of the gene. In some cells, homologous recombination occurs between the wild-type and mutant forms of gene X. Cells that can grow in the presence of kanamycin have only a single, disrupted copy of gene X. Site-directed mutagenesis is widely used to create “knockout” mutants to identify essential genes (◀ Section 10.4).

cassette mutagenesis. These cassettes can be synthesized using the polymerase chain reaction (PCR) or by direct DNA synthesis, the cost of which is now a minor laboratory expense. Once the appropriate cassette has been obtained, it can then replace sections of the DNA of interest using restriction sites or recombineering (Section 12.2) to facilitate the manipulations. Cassettes used to replace sections of genes are typically the same size as the wild-type DNA fragments they replace.

Another type of cassette mutagenesis is called **gene disruption**. In this technique, cassettes are inserted into a gene, thus disrupting the coding sequence (Figure 12.16b). Cassettes used for making insertion mutations can be almost any size and can even carry an entire gene. To facilitate selection, cassettes that encode antibiotic resistance are commonly used. For example, a DNA cassette containing a gene conferring kanamycin resistance is inserted at a restriction site in a cloned gene. The vector carrying the disrupted gene is then converted from a circular to a linear form by cutting it with a different restriction enzyme. Finally, the linear DNA is transformed into the host and kanamycin resistance is selected. The linear plasmid cannot replicate, and so resistant cells arise mostly by homologous recombination (◀ Section 9.5) between the mutated gene on the plasmid and the wild-type gene on the chromosome (Figure 12.16b). Because the gene disruption cassette is designed to contain regions of homology with the target gene that are longer than 50 base pairs, special recombinase systems used for recombineering are not needed (Section 12.2).

When a cassette is inserted, the cells not only gain antibiotic resistance but also *lose the function of the gene* into which the cassette is inserted. Such mutations are called **knockout mutations** and are widely used in biology. Knockouts are similar to insertion mutations made by transposons (◀ Section 9.11), but here the experimenter chooses which gene will be mutated. Knockout mutations in haploid organisms yield viable cells only if the disrupted gene is nonessential. Thus, gene knockouts are commonly used for determining whether a gene of interest is essential (◀ Section 10.4).

12.5 Reporter Genes and Gene Fusions

DNA manipulation has revolutionized the study of gene regulation, and *gene fusions* have been a major tool for studying regulatory events. We briefly mentioned gene fusions in our discussion of the utility of fusion proteins for stabilizing and purifying cloned gene products in Section 12.3. In a reporter gene fusion, a coding sequence from one source (the *reporter*) is fused to a regulatory region from another source to form a hybrid gene. Regulation of gene expression is then studied by assaying for the product of the reporter as a function of different conditions sensed by the regulator.

Reporter Genes

The key property of a **reporter gene** is that it encodes a protein that is easy to detect and assay. Reporter genes are used for a variety of purposes. They may be used to report the presence or absence of a particular genetic element (such as a plasmid) or DNA inserted within a vector. They can also be fused to other genes or to the promoter of other genes so that gene expression can be studied (◀ Figure 8.1).

The first widely used reporter gene was *lacZ* from *Escherichia coli*, a gene that encodes the enzyme β -galactosidase, required for lactose catabolism (◀ Section 7.3). Cells expressing β -galactosidase can be detected easily by the color of their colonies on indicator plates that contain the artificial substrate X-gal (Section 12.2); X-gal is cleaved by β -galactosidase to yield a blue color (see Figure 12.10).

The **green fluorescent protein (GFP)** is widely used as a reporter (Figure 12.17). Although the gene encoding GFP was originally cloned from the jellyfish *Aequorea victoria*, GFP can be expressed in both prokaryotic and eukaryotic cells (Figure 12.17) because it is stable and causes little or no disruption of host cell metabolism. If expression of a cloned gene is linked to the expression of GFP, the latter signals (reports) that the cloned gene has also been expressed (Figure 12.17). Since the discovery of the GFP, many similar but differently colored fluorescent proteins have been developed as reporters (◀ Section 8.1).

Gene Fusions

Gene fusions are genetic constructs that consist of segments from two different genes. If the promoter that controls a coding sequence is removed, the coding sequence can be fused to a different regulator

to place the gene under the control of a different promoter. Alternatively, the promoter region can be fused to a gene whose product is easy to assay. There are two different types of gene fusions. In **operon fusions**, a coding sequence that retains its own translational start site and signals is fused to the transcriptional signals of another gene. In **protein fusions**, genes that encode two different proteins are fused together so that they share the same transcriptional and translational start and stop signals. Following translation, protein fusions yield a single hybrid polypeptide (Section 12.3).

Gene fusions are often used in studying gene regulation, especially if measuring the levels of the natural gene product is difficult, expensive, or time consuming. The regulatory region of the gene of interest is fused to the coding sequence for a reporter gene, such as that for β -galactosidase or GFP. The reporter is then made under the conditions that would trigger expression of the target gene (Figure 12.18). The expression of the reporter is assayed under a variety of conditions to determine how the gene of interest is regulated (Chapter 7). *Transcriptional control* is assayed by fusing the transcriptional start signals of the gene of interest to a reporter gene, whereas *translational control* is assayed by fusing translational start signals of a gene of interest to a reporter gene under the control of a known promoter.

Gene fusions may also be used to test for the effects of regulatory genes. Mutations that affect regulatory genes are introduced into cells carrying gene fusions, and expression is measured and compared to cells lacking the regulatory mutations. This allows the rapid screening of multiple regulatory genes that are suspected of controlling the target gene. Besides the use of fusions to monitor for the

Figure 12.17 Green fluorescent protein (GFP). GFP can be used as a general tag or as a specific tag for protein localization. (a) Using prokaryotic cells, a plate shows uniformly green bacterial colonies because several genes were fused with the gene encoding GFP. (b) Using a eukaryotic example, the gene encoding the DNA-binding protein Pho2 from the yeast *Saccharomyces cerevisiae* was fused to the gene encoding GFP. The recombinant gene was transformed into budding yeast cells that expressed the fluorescent fusion protein only in the nucleus. Budding cell division (▶ Section 18.10 and Figures 18.27 and 18.28) is in progress in the two cells on the lower right.

Figure 12.18 Construction and use of gene fusions. The promoter of the target gene is fused to the reporter coding sequence. Consequently, the reporter gene is expressed under those conditions where the target gene would normally be expressed. The reporter shown here is an enzyme (such as β -galactosidase) that converts a substrate to a colored product that is easy to detect. This approach greatly facilitates the investigation of regulatory mechanisms.

presence or expression of a gene, fusions can also be used to join proteins that are easily purified to proteins of interest to aid in purification of the latter (Section 12.3).

We now move on from considering how genes can be manipulated to the application of gene technologies for the synthesis of valuable commercial products by genetically engineered organisms.

II • Making Products from Genetically Engineered Microbes: Biotechnology

Microbes can be altered by the genetic engineer to manufacture products such as therapeutic human proteins, vaccines, and biofuels, and genetic tools obtained from microbes can be used to create genetically novel transgenic plants and animals.

Genetic engineering can transform microorganisms into tiny factories for the production of valuable products including fuels, chemicals, drugs, and human hormones, such as insulin. This is the science of **biotechnology**. Up to this point we have only

considered the techniques used for manipulating, cloning, and expressing DNA. We now consider how these techniques are applied in biotechnology to produce valuable proteins and genetically modified plants, animals, vaccines, and metabolic pathways.

12.6 Somatotropin and Other Mammalian Proteins

One of the most economically profitable areas of biotechnology has been the production of human proteins. Many mammalian proteins have high pharmaceutical value but are typically present in very low amounts in normal tissue, and it is therefore extremely costly to purify them. Even if the protein can be produced in cell culture, this is much more expensive and difficult than growing microbial cultures that produce the protein in high yield. Therefore, the biotechnology industry has developed genetically engineered microorganisms to produce many different mammalian proteins.

Somatotropin

Although insulin was the first human protein to be produced by bacteria, the genetic engineering required was complicated because insulin consists of two short polypeptides held together by disulfide bonds. A more straightforward example is *human somatotropin* (growth hormone), which consists of a single polypeptide encoded by a single gene; a deficiency of somatotropin in the body results in hereditary dwarfism. Because the human somatotropin gene has been successfully cloned and expressed in bacteria, children showing stunted growth can be treated with *recombinant human somatotropin* to correct this. However, some forms of dwarfism are caused by a lack of the somatotropin receptor, and in such cases, administration of somatotropin has no effect.

The human somatotropin gene was cloned as complementary DNA (cDNA) from mRNA as described in Section 12.3 (see Figure 12.19). The cDNA was then expressed in a bacterial expression vector. The main problem with producing relatively short polypeptide hormones such as somatotropin is their susceptibility to protease digestion, but this problem was overcome by using bacterial host strains lacking key protease enzymes. Today recombinant human growth hormone taken by injection is marketed under several brand names in the United States and has successfully treated thousands of children afflicted with any of several different syndromes that result in short stature. Recombinant somatotropin has also been used to treat some cases of tissue atrophy in adults. However, use in adults is not a common practice, and growth hormone is banned by the International Olympic Committee and by some professional sports leagues for its alleged performance-enhancing capabilities.

Recombinant bovine somatotropin (rBST) is used in the dairy industry (Figure 12.19). Injection of rBST into cows does not make them grow larger but instead stimulates milk production. This is because somatotropin has two binding sites; one is the somatotropin receptor that stimulates growth while the other is the prolactin receptor that promotes milk production. Thus, cows treated with rBST produce more milk. However, when human somatotropin is used to treat short stature conditions, it is desirable to avoid any side effects from the hormone's prolactin activity. To alleviate this problem, site-directed mutagenesis (Section 12.4) of the human

Figure 12.19 Cloning and expression of bovine somatotropin. The mRNA for bovine somatotropin (BST) is obtained from a cow, and the mRNA is converted to cDNA by reverse transcriptase. The cDNA version of the somatotropin gene is then cloned into a bacterial expression vector that has a bacterial promoter and ribosome-binding site (RBS). The construct is transformed into cells of *Escherichia coli*, and recombinant bovine somatotropin (rBST) is produced. Milk production increases in cows treated with rBST.

somatotropin gene was used to alter those amino acids of somatotropin that bind to the prolactin receptor, thus ensuring that the hormone would only target growth. As this example shows, it is possible not only to make genuine human hormones but also to alter their specificity and activity to make them better pharmaceuticals.

Other Mammalian Proteins

Many other mammalian proteins are produced today by genetic engineering (Table 12.1). These include, in particular, an assortment of hormones and proteins for blood clotting and other blood processes. For example, *tissue plasminogen activator* (TPA) is a protein that dissolves blood clots in the bloodstream that may form in the final stages of the healing process. TPA is primarily used in heart patients or others suffering from poor circulation to prevent the development of clots that can be life-threatening. Heart disease is a leading cause of death in many developed countries, especially in the United States, so microbially produced TPA is in high demand. In contrast to TPA, the blood clotting factors VII, VIII, and IX are critically important for the *formation* of blood clots. Hemophiliacs

TABLE 12.1 A few human medical products made by genetic engineering	
Product	Function
Blood proteins	
Erythropoietin	Treats certain types of anemia
Factors VII, VIII, IX	Promotes blood clotting
Tissue plasminogen activator (TPA)	Dissolves blood clots
Urokinase	Promotes blood clotting
Human hormones	
Epidermal growth factor	Wound healing
Follicle-stimulating hormone	Treatment of reproductive disorders
Insulin	Treatment of diabetes
Nerve growth factor	Treatment of degenerative neurological disorders and stroke
Relaxin	Facilitates childbirth
Somatotropin (growth hormone)	Treatment of some growth abnormalities
Immune modulators	
α -Interferon	Antiviral, antitumor agent
β -Interferon	Treatment of multiple sclerosis
Colony-stimulating factor	Treatment of infections and cancer
Interleukin-2	Treatment of certain cancers
Lysozyme	Anti-inflammatory
Tumor necrosis factor	Antitumor agent, potential treatment of arthritis
Replacement enzymes	
β -Glucocerebrosidase	Treatment of Gaucher disease, an inherited neurological disease
Therapeutic enzymes	
Human DNase I	Treatment of cystic fibrosis
Alginate lyase	Treatment of cystic fibrosis

suffer from a deficiency of one or more clotting factors and can therefore be treated with microbially produced clotting factors. In the past hemophiliacs have been treated with clotting factor extracts from pooled human blood, some of which was contaminated with viruses such as HIV and hepatitis C, putting hemophiliacs at high risk for contracting AIDS, hepatitis, or liver cancer. Recombinant clotting factors have eliminated this problem. Some mammalian proteins made by genetic engineering are enzymes rather than hormones (Table 12.1). For instance, *human DNase I* is used to treat the buildup of DNA-containing mucus in the lungs of patients with cystic fibrosis. The mucus forms because cystic fibrosis is often accompanied by life-threatening lung infections by the bacterium *Pseudomonas aeruginosa*. The bacterial cells form biofilms (Section 8.10 and Section 20.4) within the lungs that make drug treatment difficult. DNA is released when the bacteria lyse, and this fuels mucus formation, making it difficult to breathe. DNase digests the DNA and greatly decreases the viscosity of the mucus.

- What are the major problems when manufacturing proteins in bacteria?
- Explain how an enzyme can be useful in treating a bacterial infection, such as that which occurs with cystic fibrosis.

12.7 Transgenic Organisms in Agriculture and Aquaculture

Genetic improvement of plants and animals by traditional selection and breeding has a long history, but recombinant DNA technology has led to revolutionary changes. Although the genetic engineering of higher organisms is not truly microbiology, much of the DNA manipulation leading up to the genetically engineered plant or animal is carried out using bacteria and the techniques we have learned thus far. Hence, we consider the genetic manipulation of plants and animals here with a focus on the microbiology that supported it.

Because genetically engineered plants or animals contain a gene from another organism—called a *transgene*—they are **transgenic organisms**. The public knows these as **genetically modified organisms (GMOs)**. Strictly speaking, the term *genetically modified* refers to genetically engineered organisms whether or not they contain foreign DNA. In this section we discuss how foreign genes are inserted into plant and fish genomes and how transgenic organisms may be used.

The Ti Plasmid and Transgenic Plants

While recombinant DNA can be transformed into plant cells by electroporation or transfection, the **Ti plasmid** from the gram-negative bacterium *Agrobacterium tumefaciens*, a plant pathogen, can be used to transfer DNA directly into the cells of certain plants. This plasmid is responsible for *A. tumefaciens* virulence and encodes genes that mobilize DNA for transfer to the plant, which as a result

contracts crown gall disease (► Section 23.6). The segment of the Ti plasmid DNA that is actually transferred to the plant is called **T-DNA**. The sequences at the ends of the T-DNA are essential for transfer, and the foreign DNA to be transferred must reside between these ends.

One common Ti-vector system that has been used for the transfer of genes to plants is a two-plasmid system called a *binary vector*, which consists of a cloning vector plus a helper plasmid. The cloning vector is a shuttle vector (Section 12.2) that contains the two ends of the T-DNA flanking a multiple cloning site, two origins of replication so that it can replicate in both *Escherichia coli* (the host for cloning) and *A. tumefaciens*, and two antibiotic resistance markers, one for selection in plants and the other for selection in bacteria. The foreign DNA is inserted into the vector, which is transformed into *E. coli* and then moved to *A. tumefaciens* by conjugation (Figure 12.20).

This cloning vector lacks the genes needed to transfer T-DNA to a plant. However, when placed in an *A. tumefaciens* cell that contains a suitable helper plasmid, the T-DNA can be transferred to a plant. The “disarmed” helper plasmid, called *D-Ti*, contains the virulence (*vir*) region of the Ti plasmid but lacks the T-DNA. It also lacks the genes that initiate disease but supplies all the functions needed to transfer the T-DNA from the cloning vector. The cloned DNA and the kanamycin resistance marker of the vector are mobilized by D-Ti and transferred into a plant cell where they enter the nucleus (Figure 12.20d). Following integration into a plant chromosome, the foreign DNA can be expressed and confer new properties on the plant.

A number of transgenic plants have been produced using the Ti plasmid of *A. tumefaciens*. The Ti system works well with broadleaf plants (dicots), including crops such as tomato, potato, tobacco, soybean, alfalfa, and cotton. It has also been used to produce transgenic trees, such as walnut and apple. The Ti system does not work with plants from the grass family (monocots, including the important crop plant corn), but other methods of introducing DNA, such as transfection by microprojectile bombardment with a particle gun (Figure 12.21), have been used successfully for them.

Figure 12.20 Production of transgenic plants using a binary vector system in *Agrobacterium tumefaciens*. (a) Plant cloning vector containing ends of T-DNA (red), foreign DNA, origins of replication, and resistance markers. (b) The vector is transformed into cells of *Escherichia coli* for cloning and then (c) transferred to *A. tumefaciens* by conjugation. The resident Ti plasmid (D-Ti) has been genetically engineered to remove key pathogenesis genes. (d) D-Ti can still mobilize the T-DNA region of the vector for transfer to plant cells grown in tissue culture. (e) From the recombinant plant cell, a whole plant can be grown. (Details of Ti plasmid transfer from bacterium to plant are shown in Figure 23.26.)

Figure 12.21 DNA gun for transfection of eukaryotic cells. The inner workings of the gun show how metal pellets coated with nucleic acids (microprojectiles) are propelled at target cells. (a) Before firing and (b) after firing. A shock wave due to gas release propels the disk carrying the microprojectiles against the fine screen. The microprojectiles continue on into the target tissue.

Herbicide- and Insect-Resistant Plants

Major areas targeted for genetic improvement in plants include herbicide, insect, and microbial disease resistance, as well as improved product quality. The main genetically modified (GM) crops today are soybeans, corn, cotton, and canola. Almost all the GM soybeans and canola planted in the United States are herbicide resistant, whereas the corn and cotton are herbicide resistant or insect resistant, or both.

Herbicide resistance is genetically engineered into a crop plant to protect it from herbicides applied to kill weeds. Many herbicides inhibit a key plant enzyme or protein necessary for growth. For example, the herbicide *glyphosate* (RoundupTM, made by Monsanto) kills plants by inhibiting an enzyme necessary for making aromatic amino acids. Some bacteria contain an equivalent enzyme and are also killed by glyphosate. However, mutant bacteria were selected that were resistant to glyphosate and contained a resistant form of the enzyme. The gene encoding this resistant enzyme from *A. tumefaciens* was cloned, modified for expression in plants, and transferred (Figure 12.20) into important crop plants, such as soybeans. When sprayed with glyphosate, plants containing the bacterial gene are not killed (Figure 12.22). Thus glyphosate can be used to kill weeds that compete for water and nutrients with the growing crop plants. Herbicide-resistant soybeans are now widely planted in the United States, including plants resistant to both glyphosate and a second widely used herbicide, dicamba.

Transgenic plants resistant to damage by certain insects have also been produced by genetic engineering (Figure 12.23). One widely used approach is based on introducing genes encoding the toxic proteins of the gram-positive, endospore-forming bacterium *Bacillus thuringiensis* into plants. As it sporulates, *B. thuringiensis* produces a crystalline protein called *Bt toxin* (► Section 16.8) that is toxic to

Figure 12.22 Transgenic plants: herbicide resistance. The photograph shows a portion of a field of soybeans that has been treated with RoundupTM, a glyphosate-based herbicide manufactured by Monsanto Company (St. Louis, Missouri, USA). The remnants of plants on the right are normal soybeans; the plants on the left have been genetically engineered to be glyphosate resistant.

moth and butterfly larvae. Many variants of Bt toxin exist that are specific for different insects. Certain strains of *B. thuringiensis* produce additional proteins toxic to beetle and fly larvae and mosquitoes.

The Bt transgene is normally inserted directly into the plant genome. For example, a natural Bt toxin gene was cloned into a plasmid vector under control of a chloroplast ribosomal RNA promoter and then transfected into tobacco plant chloroplasts by microprojectile bombardment (Figure 12.21). This yielded transgenic plants that expressed Bt toxin at levels that were extremely toxic to larvae of several insect species (Figure 12.23). Binding Bt triggers a change in the toxin's conformation that disrupts the insect digestive system, causing death. Bt toxin is harmless to mammals (including humans) because any toxin ingested is destroyed in the stomach and the specific Bt receptors in the insect intestine are absent from the intestines of other groups of organisms.

Effect of insect larvae

Figure 12.23 Transgenic plants: insect resistance. The results of an assay to determine the effect of beet armyworm larvae on tobacco leaves. (a) Leaf from a wild-type plant. (b) Leaf from a transgenic plant expresses Bt toxin in its chloroplasts and the toxin kills the larvae.

Despite the toxicity and availability of numerous Bt variants, insect resistance to the toxin is emerging. This is especially problematic with corn rootworms. To combat resistance issues, plant engineers are looking at other soil microbes for the production of different types of insecticidal proteins. This has resulted in the discovery of a small insecticidal peptide from the gram-negative soil-dwelling *Pseudomonas chlororaphis*. Transfer of the gene encoding the peptide into corn using an *Agrobacterium*-mediated system (Figure 12.20) resulted in protection from the rootworm. While the mechanism by which the *P. chlororaphis* peptide kills rootworms is not completely understood, the peptide kills Bt-resistant rootworms but does not affect other common insects such as bees and other pollinators. Thus, a new weapon is now available to specifically combat corn rootworm and may help to retard the development of resistance in this potentially devastating crop pest.

Transgenic Fish

Many foreign genes have been incorporated and expressed in laboratory research animals and in commercially important animals. The genetic engineering uses microinjection to deliver cloned genes to fertilized eggs; genetic recombination then incorporates the foreign DNA into the genomes of the eggs. More recently, farm animals and fish have been genetically modified to improve yields.

An interesting practical example of a transgenic animal is the *AquaAdvantage* salmon developed by AquaBounty Technologies (Figure 12.24). These transgenic salmon do not grow to be larger than normal salmon but simply reach market size much faster—18 months versus 3 years. The gene for growth hormone in native salmon is activated by light. Consequently, salmon grow rapidly only during the summer months. In the genetically engineered salmon, the promoter for the growth hormone gene was replaced with the promoter from another fish that grows at a more or less constant rate all year round. The result was salmon that make growth hormone continuously and thus grow faster. Such transgenic salmon can be grown commercially in aquaculture operations and harvested more quickly than with non-GMO farm-raised salmon.

In 1995 AquaBounty applied to the U.S. Food and Drug Administration (FDA) for approval to distribute the fast-growing salmon. After two decades of debate regarding the potential risks of consuming genetically modified fish, approval for its distribution occurred

Figure 12.24 Fast-growing transgenic salmon. The AquaAdvantage™ salmon (top) was engineered by AquaBounty Technologies (Maynard, Massachusetts, USA). The transgenic and control fish are both 18 months old but weigh 4.5 kg and 1.2 kg, respectively.

in 2015. However, in response to remaining concerns regarding the sale of the modified salmon, the United States enacted a law at the end of 2015 that prohibited its sale until labeling could be agreed upon. However, in early 2019, the FDA removed the final hurdle to the sale of GMO salmon in the United States, and it can now be sold (marketed as AquaAdvantage® salmon and containing a label indicating that it is a bioengineered product).

12.8 Engineered Vaccines and Therapeutic Agents

Genetic engineering is used to manufacture certain vaccines and medical therapeutic agents. Of interest to human health and biotechnology are the two types of relationships microbes form within the human body. While some microbes form beneficial relationships within humans by aiding digestion, producing nutrients, and “educating” the immune system (► Section 24.2), other microbes cause disease through their ability to infiltrate cells and release virulence factors such as toxins and destructive enzymes. With this in mind, scientists have explored the use of both types of microbial communities for making novel vaccines and for delivering drugs or toxic agents to specific cell types. We consider both of these potential medical miracles here.

Recombinant Vaccines, Vaccinia Virus, and Subunit Vaccines

Vaccines are substances that elicit immunity to a disease when injected into an animal (► Section 28.3). Genetic engineering can modify a pathogen by deleting genes from its genome that encode virulence factors (► Section 25.5) while retaining those whose products elicit an immune response. This yields a recombinant and infective vaccine that is considered **attenuated** because it is less virulent than the original strain (► Section 25.3 and Figure 25.10). Conversely, one can add genes from a pathogenic virus to the genome of a relatively harmless virus, called a *carrier virus*. Such vaccines are called **vector vaccines** and induce immunity to the pathogenic virus. Indeed, one can even combine the two approaches by disarming one pathogen and adding back to it immunity-inducing genes from a second pathogen. This yields a **polyvalent vaccine**, a vaccine that immunizes against two different diseases at the same time.

Vaccinia virus (◄ Section 11.6) is widely used to prepare recombinant vaccines for human use; however, cloning into vaccinia requires a selective marker, which is provided by the gene encoding the enzyme thymidine kinase. Vaccinia virus contains a gene encoding thymidine kinase, an enzyme that converts thymidine into thymidine triphosphate. However, this enzyme also converts the base analog 5-bromodeoxyuridine (BrdU) into a nucleotide that is incorporated into DNA, causing a lethal reaction. Thus, cells that express either host- or virus-encoded thymidine kinase are killed when treated with BrdU.

Figure 12.25 Production of recombinant vaccinia virus. Foreign DNA is inserted into a short segment of the thymidine kinase gene (*tdk*) from vaccinia virus carried on a plasmid. Following replication of this plasmid in *Escherichia coli*, both the recombinant plasmid and wild-type vaccinia virus are put into the same animal host cell to promote recombination. The animal cells are treated with 5-bromodeoxyuridine (BrdU), which kills only cells with an active thymidine kinase. Only recombinant vaccinia viruses whose *tdk* gene is inactivated by insertion of foreign DNA survive.

Genes to be put into the vaccinia virus genome are first inserted into an *Escherichia coli* plasmid that contains part of the vaccinia thymidine kinase (*tdk*) gene (Figure 12.25). The foreign DNA is inserted into the *tdk* gene, which is therefore disrupted. This recombinant plasmid is then transformed into animal cells whose own *tdk* genes have been inactivated. These cells are also infected with wild-type vaccinia virus. The two versions of the *tdk* gene—one on the plasmid and the other on the virus—then recombine. Some viruses gain a disrupted *tdk* gene plus its foreign insert (Figure 12.25). Cells infected by wild-type vaccinia virus (with an active thymidine kinase) are killed by BrdU. By contrast, cells infected by recombinant vaccinia virus (with a disrupted *tdk* gene) grow long enough to yield a new generation of virus particles (Figure 12.25). This protocol thus selects for viruses whose *tdk* gene contains a cloned insert of foreign DNA. Vaccinia viruses can also be engineered to carry genes from multiple viruses, forming polyvalent vaccines. Currently, several vaccinia vector vaccines have been developed and licensed for veterinary use, including one for rabies, while many other vaccinia vaccines are at the clinical trial stage.

Subunit vaccines, vaccines that contain only a specific protein or two from a pathogen, are also produced by recombinant means. For a pathogenic virus, the gene encoding its coat or capsid protein is often the best vaccine candidate because capsid proteins are typically highly immunogenic (◀ Section 5.1 and ▶ Section 28.3). Subunit vaccines are popular because large amounts of immunogenic proteins are produced that can be administered at high dosage without the risk that exists with attenuated or killed-cell vaccines that may inadvertently contain viable pathogen cells or viruses. However, some subunit vaccines, such as that prepared against a surface protein of human hepatitis B (▶ Section 31.11), require that the immunogenic proteins be glycosylated by the host before they are immunologically active. To solve this problem, the subunit hepatitis B vaccine was produced in a eukaryotic host (yeast), which generated the glycosylated and immunologically active form of the vaccine.

Commensal Bacteria and Therapeutic Delivery

While new therapeutic agents to treat different diseases are constantly being developed, *delivery* to the target tissues or cells can be problematic. This is especially true for drugs that are rapidly degraded in the bloodstream or by the acidity of the stomach. To alleviate these problems, members of the microbiome that form positive relationships in the body—such as the gut normal flora—have been exploited to produce and release drugs while inside a host (Figure 12.26). Because of their commensal lifestyle, these microbes do not illicit an immune response and are tolerated well by the body. For therapeutic delivery of *anticancer* drugs, members of the microbiome that flourish in anaerobic niches such as the intestinal tract and in tumors are of particular interest. Tumors become anaerobic because of rapid cell proliferation, which results in the tumor rapidly outgrowing its blood supply. Dying tumor cells also release nutrients that attract members of the microbiome. Through genetic engineering, some of these bacteria that are naturally tolerated by the body and colonize tumors have been harnessed to not only deliver therapeutic substances specifically to diseased or cancerous cells (Figure 12.26a), but also to release tumor-specific antigens within circulating immune cells to facilitate the immune system's targeting of tumors (see below and Figure 12.26b).

An exciting example of the targeted delivery of a *beneficial* drug is the use of engineered commensal bacteria to convert intestinal cells into glucose-responsive insulin-secreting cells. In type 1 (juvenile) diabetes mellitus, the immune system destroys insulin-producing beta cells in the pancreas (▶ Section 28.1). Studies on how to generate new beta cells are under way; meanwhile, different studies have focused on ways to convert other cell types into insulin producers. From these studies, a therapeutic molecule known as the full-length glucagon-like peptide 1 (GLP1) has been shown in a rat diabetes model to be able to reprogram intestinal epithelial cells to respond to glucose and produce insulin. However, GLP1 has a short half-life in the bloodstream and the target epithelial cells are

Figure 12.26 Strategies for bacterial delivery of therapeutic agents. (a) Pathogens that grow in the low-oxygen environment of a tumor can be attenuated and genetically modified to release drugs directly inside tumors. (b) Pathogens that elicit a strong immune response can be attenuated and engineered to release antigens normally found on tumor cells. This antigen release stimulates antibody production and immune system destruction of tumors. (c) Probiotic strains normally found in the healthy gut can be engineered to release therapeutic molecules to treat various diseases as well as help train the immune system to tolerate beneficial microbes.

naturally shed from the intestine over the course of days. Thus, to deliver GLP1 to intestinal epithelial cells on a continuous basis, genetic engineers modified a strain of *Lactobacillus*, a gram-positive bacterium that can propagate in the intestine, to constitutively secrete GLP1 in the gut (Figure 12.26c). While this work has only been done in an experimental animal, it offers promise for the future of treating diabetes in humans.

Probiotics are live commensal microorganisms administered to a human to benefit health (► Section 24.12), and engineered probiotics have been used to sense and kill biofilm-forming strains of *Pseudomonas aeruginosa*. The ability to sense *P. aeruginosa* is based on its production of the quorum-sensing inducer molecule *N*-acyl homoserine lactone (AHL; ◀ Section 7.7). A probiotic strain of *Escherichia coli* has been modified not only to sense *P. aeruginosa*, but also to release a cocktail of therapeutic substances in response to AHL levels. These include a dispersin molecule to destroy *P. aeruginosa* biofilms, as well as bacteriocin (◀ Section 6.2) and lysis proteins to specifically kill *P. aeruginosa*

cells. **Figure 12.27** illustrates the success of this engineered probiotic in a worm experimental model infected with *P. aeruginosa* producing green fluorescent protein (GFP, Section 12.5 and Figure 12.17). While *P. aeruginosa* can successfully colonize the host worm in the presence of a wild-type strain of *E. coli* (Figure 12.27a), the pathogen cannot colonize the host worm in the presence of an engineered strain of *E. coli* releasing therapeutic molecules in response to *P. aeruginosa* AHL levels (Figure 12.27b). A major goal of such research is to develop new tools to fight the human genetic disease cystic fibrosis, a disease in which *P. aeruginosa* biofilms in the lungs are a life-threatening complication.

Pathogens as Engineered Anticancer Therapies

While many cancers are treatable with radiation and chemotherapy, how to specifically target the immune system, drugs, or radiation to tumor cells has been a long-standing problem, and biotechnology may have a solution. *Listeria monocytogenes* is a pathogenic bacterium that causes listeriosis, a serious foodborne illness (► Section 33.13 and Figures 33.14 and 33.15). *L. monocytogenes* grows within human cells, which allows wild-type strains to evade the immune system. By contrast, attenuated strains of *L. monocytogenes* can be attacked by the immune system. These traits have been harnessed to engineer recombinant *L. monocytogenes* strains that express antigens found on tumor cells. The presence of these tumor-associated antigens triggers the immune system to produce tumor-specific antibodies

Figure 12.27 Probiotic *Escherichia coli* engineered to kill *Pseudomonas*. Infection of the worm *Caenorhabditis elegans* with biofilm-forming *P. aeruginosa* expressing the green fluorescent protein (GFP) and treatment with an engineered strain of *E. coli*. (a) Active *P. aeruginosa* infection (visualized by GFP production) in the presence of a probiotic (attenuated) strain of *E. coli* (top, fluorescent micrograph; bottom, phase-contrast micrograph). (b) Limited *P. aeruginosa* survival occurs in response to the addition of the engineered version of the *E. coli* probiotic strain. The engineered strain was genetically modified to release therapeutic molecules that disrupt biofilms and kill *P. aeruginosa* cells when a quorum-sensing molecule produced by *Pseudomonas* is detected. Image adapted from Hwang, I.Y., Koh, E., Wong, A., March, J.C., Bentley, W.E., Lee, Y.S., and Chang, M.W. 2017. *Nat. Commun.* 8: 15028.

Dinesh Chandra and Claudia Gravekamp

Figure 12.28 Therapeutic *Listeria*. *L. monocytogenes* cells (pink) linked to the radionuclide $^{188}\text{rhenium}$ enter and multiply inside mouse pancreatic tumor cells (blue, cells; green, extracellular matrix) that have spread from the primary tumor. Radiation from the $^{188}\text{rhenium}$ slowly kills the tumor cells.

(Figure 12.26b), and these ultimately lead to destruction of not only the bacterium but also the tumor. An example of such a tumor-targeting bacterial vaccine is an engineered strain of *L. monocytogenes* that expresses antigens specific to tumors caused by the human papillomavirus (HPV, ► Section 31.14).

While attenuated *L. monocytogenes* strains in healthy cells are cleared by the immune system, clearance does not occur in tumor cells. This observation hinted that weakened strains of *L. monocytogenes* might also be turned into anticancer vehicles to deliver toxic drugs or radioisotopes specifically to tumor cells. This was accomplished by coupling the radionuclide $^{188}\text{rhenium}$ to a recombinant strain of *L. monocytogenes*. In experiments with mice, this therapeutic strain infected and multiplied in pancreatic tumor cells (Figure 12.28)

Engineered
anthrax toxin

Figure 12.29 Engineered anthrax toxin. The protective antigen component of the anthrax toxin is engineered to carry a synthetic antibody. This engineered protective antigen specifically binds to a cell receptor on target cancer cells. After binding to the receptor, the engineered complex is taken up into the cell through an endosome. Following release into the cytoplasm, the synthetic antibody binds to an essential cellular protein, triggering the cancer cell's death through the host's immune response. (Anthrax toxin is discussed in more detail in Sections 30.9 and 32.8.)

without harming normal pancreatic cells. In Section 12.11 we will pick up on this theme again and describe how synthetic biology has been used not only to attenuate a pathogen to persist in tumor cells, but also to contain a synthetic biological circuit for the cyclical delivery of an antitumor drug to minimize drug toxicity to the rest of the body (see Figure 12.39).

Specific Delivery of Antibodies as an Anticancer Therapy

Another mechanism for treating cancer is by using antibodies, proteins produced by the immune system to attack foreign substances (► Section 27.3). It has been found that the binding of antibodies to specific targets inside cancer cells can trigger the host's immune system to kill the cancer cell. However, antibodies do not freely enter cells and thus a transport mechanism has been genetically engineered using a toxin produced by *Bacillus anthracis*, the bacterium that causes anthrax (► Sections 30.9 and 32.8) (Figure 12.29). Anthrax toxin contains three components: edema factor, lethal factor, and protective antigen; the latter is essential for carrying the toxic edema and lethal factors into the cell.

Using genetic engineering, scientists have modified the *B. anthracis* protective antigen to carry a *synthetic anticancer antibody* instead of the toxic edema and lethal factors. Injection of the modified and now harmless toxin results in the protective antigen recognizing and binding to a receptor on the outside of the cancer cell (Figure 12.29). The protective antigen:antibody complex is then taken up into the cancer cell through the formation of an endosome. Once the antibody is released into the cytoplasm, it specifically binds a protein essential to tumor viability. This binding then triggers the cell's immune system, which recognizes the antibody:cellular protein complex as foreign and kills the cell (Figure 12.29). Any antigen:antibody complex incorporated by normal cells is harmless because both the toxic portions of the toxin and the specific cancer proteins targeted by the antibody are absent from normal cells.

Stimulating the immune system to fight cancer may well turn out to be a mechanism in a whole new line of anticancer therapies. The novel system devised here—combining antitumor antibodies with a delivery system crafted from a highly toxic bacterium—shows both the power and the promise of genetic engineering to accelerate the war on cancer. The immunological principles behind this and other important new anticancer therapies will be developed in Chapter 28.

We now transition from medical applications of genetic engineering to consider commercial applications in the final two sections of Part II of the chapter.

12.9 Mining Genomes and Engineering Pathways

Complex environments, such as fertile soil, contain vast numbers of uncultured microbes and their genes that are ripe for harvesting by genetic engineering. In addition, microbial metabolic pathways can be altered, embellished, or otherwise modified to change their characteristics and improve their efficiency. Here we explore how genetic engineering can both mine environmental genomes and alter metabolic pathways.

Environmental Gene Mining

Just as the total gene content of an organism is its *genome*, the collective genomes of an environment are its *metagenome* (◀ Section 10.7 and ▶ Section 19.8). *Gene mining* is the process of identifying and

isolating potentially useful genes from the environment without the need to culture the organisms that contained them. In gene mining, DNA (or RNA) isolated directly from environmental samples is cloned into suitable vectors to construct a *metagenomic library* (Figure 12.30). If RNA is isolated, it must first be converted to cDNA by reverse transcriptase (Figure 12.3).

Screening of environmental metagenomic libraries has identified novel genes encoding enzymes that can degrade various pollutants and enzymes that make novel antibiotics. Retrieval of gene clusters encoding entire metabolic pathways—such as for antibiotic synthesis—requires vectors such as **bacterial artificial chromosomes (BACs)** (we discussed the general principles of artificial chromosomes in Section 12.2). BACs are similar to plasmids except that they can carry large inserts of DNA. BACs are especially useful for screening samples from rich environments, such as soil, where vast numbers of unknown genomes are present and correspondingly large numbers of genes are available to screen (Figure 12.30).

Several lipases, chitinases, esterases, and other degradative enzymes with novel substrate ranges and other properties have been isolated by this approach, and such enzymes have many industrial applications. Enzymes with improved resistance to industrial production conditions, such as high temperature, high or low pH, and oxidizing conditions, are especially valuable and desirable. Metagenomics can also target products with a particular combination of properties, such as a heat-stable lipase. Lipases hydrolyze fats, but their industrial production and use often require that they remain active at high temperatures. To isolate a thermostable lipase, a metagenomic library was prepared from a hot spring sample and the DNA was transformed into cells of *Escherichia coli*. Recombinant colonies expressing lipase activity were then selected and analyses indicated that certain of them remained active at 90°C. The gene encoding the heat-stable lipase was then introduced into an expression vector for commercial production of the enzyme.

Figure 12.30 Metagenomic search for useful genes in the environment. DNA samples are obtained from different environments, such as seawater, forest soil, and agricultural soil. A metagenomic library is constructed using bacterial artificial chromosomes (BACs) and screened for genes of interest. Possibly useful clones are analyzed further.

Figure 12.31 Application of CinderBio hyperstable enzymes for the cleaning of creamery equipment. These heat-stable enzymes clean industrial food-processing equipment as well as or better than traditional cleaning methods and do not generate large amounts of toxic wastewater.

By metagenomic mining of extreme environments, several useful heat- and acid-stable enzymes have been isolated for cleaning food-processing equipment in the food industry (Figure 12.31). To prevent foodborne infections, food-processing equipment must be rigorously cleaned, and cleaning protocols typically employ rigorous acid and base treatments, detergents, and sanitizers, all of which consume large amounts of chemicals and generate large volumes of wastewater that must be treated. By contrast, cleaning equipment with enzymes that function optimally near the boiling point of water in dilute acids (Figure 12.31) requires fewer chemicals and less water and more effectively removes microbial biofilms than standard cleaning practices.

Pathway Engineering: The Indigo Synthesis Example

Pathway engineering is the process of assembling a new or improved biochemical pathway using genes from one or more organisms. Engineered microbes are used to make alcohols, solvents, food additives, dyes, antibiotics, and many other products. They may also be used to degrade agricultural waste, pollutants, herbicides, and other toxic or undesirable materials. Here we discuss improving or modifying *existing pathways*, and later we explore the use of synthetic biology to create *entirely new pathways* (Section 12.11).

An interesting example of pathway engineering is the production of indigo by *E. coli* (Figure 12.32). Indigo is an important dye used for treating wool and cotton; blue jeans, for example, are made of cotton dyed with indigo. Although indigo can be synthesized chemically, the heavy demand for indigo by the textile industry has spawned new approaches for its synthesis, including a biotechnological approach using pathway engineering.

Because the structure of indigo is very similar to that of the aromatic hydrocarbon naphthalene, enzymes that oxygenate naphthalene also oxidize indole to its dihydroxy derivative; the latter oxidizes spontaneously in air to yield indigo, a bright blue pigment. Enzymes for oxygenating naphthalene are encoded by several plasmids found in *Pseudomonas* and other soil bacteria. When genes from such plasmids were cloned into *E. coli*, the cells turned blue because they had incorporated the genes encoding the enzyme naphthalene oxygenase.

The indigo pathway consists of four steps, two enzymatic and two spontaneous (Figure 12.32). *E. coli* naturally synthesizes the enzyme tryptophanase that carries out the first of these steps, the conversion of tryptophan to indole. In the engineered *E. coli*, a second step converts indole to the product that converts to indigo spontaneously (Figure 12.32). For indigo production, tryptophan must be supplied to the recombinant *E. coli* cells, and for commercial application, this was accomplished by affixing cells to a solid support in a bioreactor and then continuously trickling a tryptophan solution obtained from waste protein sources over the cells. If the tryptophan solution is recirculated over the cells several times, indigo levels steadily increase until the dye can be harvested.

Although bioproduction of indigo is clearly possible, at present it is difficult to compete with the chemical production of more than 20 kilotons of indigo per year. Indeed, the two greatest challenges of pathway engineering are controlling the pathway and producing the desired compound at the yields necessary to be cost effective.

Check Your Understanding

- Explain why metagenomic cloning gives large numbers of novel genes.
- What types of environments are often sampled to prospect for industrial enzymes and why?
- How was *Escherichia coli* modified to produce indigo?

Figure 12.32 Engineered pathway for production of the dye indigo. *Escherichia coli* naturally expresses tryptophanase, which converts tryptophan into indole. Naphthalene oxygenase (originally from *Pseudomonas*) converts indole to dihydroxy-indole, which spontaneously dehydrates to indoxyl. Upon exposure to air, indoxyl dimerizes spontaneously to form indigo.

12.10 Engineering Biofuels

With the global supply of fossil fuels limited and environmental concerns growing about how climate change will affect our planet, renewable energy sources such as biologically produced fuels—*biofuels*—are in demand. The major biofuels in use today are ethanol, biodiesel, hydrogen, and methane. Select microorganisms can produce biofuels; however, the yield from wild-type organisms is often hindered by side reactions, toxic by-products, and missing enzymes for critical steps. For example, hydrogen (H_2) is produced by nitrogen-fixing bacteria through the activity of a nitrogenase enzyme complex (◀ Figure 3.28). However, most of this hydrogen is subsequently consumed by hydrogenase enzymes in wild-type nitrogen fixers. Thus, to enhance the production of biofuels, microorganisms have been genetically modified to optimize production. Here we discuss how genetic engineering has allowed for the use of alternative biofuel feedstocks, how enzyme replacement can yield new biofuels, and how phototrophic microorganisms can be harnessed as biofuel factories.

Bacterial Conversion of Switchgrass to Ethanol

Over 16 billion gallons of ethanol are produced per year in the United States from the fermentation of corn sugar by yeast (Figure 12.33a). However, because corn requires considerable cost and energy inputs to grow and harvest and is a major food source for both humans and domesticated animals, alternative nonedible and low-resource-input plant materials are more desirable biofuel feedstocks. Much attention has been focused on fast-growing grasses such as *switchgrass* (*Panicum virgatum*) (Figure 12.33b) as a source of cellulose for the production of ethanol. However, switchgrass cellulose is integrated with other plant polymers such as hemicellulose and lignin and requires high-temperature, chemical, and enzymatic pretreatment to break the polymers down to fermentable sugars.

By tapping into both microbial diversity and genetic engineering, a bacterium has been discovered and genetically modified not only to break down switchgrass cellulose to fermentable sugars but also to ferment this sugar to ethanol. *Caldicellulosiruptor*, a gram-positive anaerobic and thermophilic bacterium, naturally produces cellulase and hemicellulase enzymes that can convert cellulose and hemicellulose to glucose. Unique proteins called *tāpirins* that extrude from

the outer layer of the bacterium's peptidoglycan allow the cell to directly bind to raw switchgrass during the conversion process (Figure 12.33c). While *Caldicellulosiruptor bescii* grows optimally at 80°C and can ferment sugars, it naturally yields mostly acetate, lactate, and hydrogen as fermentation products. To directly convert switchgrass to ethanol, genetic engineers altered the terminal steps of the *C. bescii* glycolytic pathway (◀ Section 3.6 and Figure 3.11) by replacing genes encoding lactate dehydrogenase and other acidic fermentation products with a bifunctional acetaldehyde/alcohol dehydrogenase from another thermophile, *Clostridium thermocellum*. This shifted 70% of the *C. bescii* fermentation products to ethanol.

Use of thermophilic microorganisms for biofuel production has several advantages such as reduced risk of contamination with mesophiles and improved substrate solubility. It also makes the collection of any volatile products easier. For example, separating small amounts of desired products from large amounts of growth media (such as collecting ethanol during yeast fermentation of corn sugar) requires significant energy inputs to cool the bioreactors for growth of the organism and then later to heat and distill off the ethanol (Figure 12.33a). By contrast, since *C. bescii* grows optimally at 80°C—just above the boiling point of ethanol—commercial production of alcohol from cellulose by this genetically engineered bacterium requires little or no cooling and saves energy by the continuous emission of the desired product, ethanol.

Engineered Alkenes and Alkanes

Petroleum contains a mixture of hydrocarbons of varying chain length. Propane (C_3H_8), produced from natural gas processing and petroleum refining, is a widely used heating and cooking fuel and a key fuel for agricultural applications. Using genetic engineering, scientists have modified strains of *Escherichia coli* to convert glucose into propane and some other petroleum hydrocarbons.

Hydrocarbon production in *E. coli* begins with the synthesis of a fatty aldehyde. This was done by heterologously expressing in *E. coli* the *Photorhabdus luminescens luxCED* genes, which encode enzymes that reduce fatty acids to their corresponding aldehydes (Figure 12.34). The activity of these fatty acid reductase, synthetase, and transferase enzymes yields a fatty aldehyde that can be converted to hydrocarbons

(c) Fluorescence photomicrograph of acridine orange-stained cells of the thermophilic and cellulolytic bacterium *Caldicellulosiruptor kronotskyensis* growing on switchgrass (a single cell measures about $0.6\ \mu m \times 3\ \mu m$). The green color is from the switchgrass plants.

S.E. Blumer-Schuetz, J.W. Zurawski, J.M. Conway, and R.M. Kelly

Figure 12.34 Hydrocarbon-producing *Escherichia coli*. *E. coli* naturally produces fatty acids from acetyl-CoA. By engineering a strain to express the LuxC (fatty acid reductase), LuxE (fatty acid synthetase), and LuxD (fatty acid transferase) proteins from the fluorescent bacterium *Photorhabdus luminescens* (inset: fluorescent colony), a fatty aldehyde intermediate is produced. This fatty aldehyde can then be converted to a hydrocarbon if the same strain has also been engineered to express the aldehyde decarbonylase enzyme from the filamentous cyanobacterium *Nostoc punctiforme* (inset photo).

by the enzyme aldehyde decarbonylase. However, *E. coli* lacks this enzyme as well. To overcome this limitation, genetic engineers cloned the aldehyde decarbonylase gene from the cyanobacterium *Nostoc punctiforme* into *E. coli*, allowing the engineered *E. coli* to convert linear fatty acids added to its growth medium into linear hydrocarbons (Figure 12.34).

Because branched-chain hydrocarbons yield higher octane numbers (which is good for gasoline engine performance), scientists expanded this engineered pathway by heterologously expressing enzymes that participate in the first step of the fatty acid elongation cycle (◀ Figure 3.35) from *Bacillus subtilis*. This allowed the engineered *E. coli* to use more branched-chain fatty acids as starting substrates and by doing so generate higher-octane fuels.

Microalgae and Biodiesel

Microalgae are unicellular phototrophic eukaryotes (▶ Section 18.16) that produce an abundance of bioactive compounds including lipids, fatty acids, and carotenoids. These products are made using only sunlight, CO₂, a few minerals, and water. Microalgae of interest to biotechnology include the green algal genera *Chlorella* and *Chlamydomonas*. These organisms produce significant amounts of storage lipids known as *triacylglycerides* (TAG), substances that can be chemically or enzymatically treated to yield *biodiesel*, a fuel for use in the diesel engines present in many trucks and heavy transport vehicles.

Improving TAG synthesis in the microalgal biosynthetic pathway required some genetic engineering breakthroughs, and Figure 12.35a illustrates the successful design of vectors that allow proteins to be targeted to the nucleus or chloroplast of cells of *Chlamydomonas*; other vectors have been developed that allow the mitochondrion or the endoplasmic reticulum to be targeted. Organelle targeting is facilitated through the fusion of *signal sequences* (◀ Section 6.12) to the protein of interest. A vector for the simultaneous expression of two foreign genes in separate cellular locations has also been generated (Figure 12.35b). These targeting vectors are critical for manipulating compartmentalized TAG biosynthetic activities such as control of gene expression by transcription factors (encoded by the nuclear genome), ATP-producing enzymes (encoded by the mitochondrial genome), and enzymes for initial fatty acid synthesis reactions

Figure 12.35 Genetic tools for engineering microalgae. (a) Fluorescent micrographs showing the expression of reporter genes in targeted regions of cells of *Chlamydomonas*. Top panel: A reporter gene encoding a red fluorescent protein that targets the nucleus (left) and chloroplasts (right). Bottom panel: both images overlaid with a green fluorescent stain for the chloroplast. (b) Dual expression of two reporter genes to different cellular locations using a single vector. A gene encoding a blue fluorescent protein is localized to the nucleus, while a gene encoding a red fluorescent protein is targeted to the endoplasmic reticulum in cells of *Chlamydomonas*. (encoded by the chloroplast genome). Translation of proteins by ribosomes on the endoplasmic reticulum is also important for protein secretion.

Using microalgal triacylglycerides as a feedstock for biodiesel increases the possibilities for biofuel production, and the fact that the process is driven by the energy of sunlight makes it an environmentally attractive process. However, the major obstacle facing all biofuel production schemes—especially those that require sunlight—is the expense of the equipment and engineering necessary to scale production up to levels necessary to compete with the petroleum industry. Currently, about 90 million barrels of oil a day arrive on the highly volatile world energy market, and until oil supplies diminish to the point where a significant price hike is encountered, any biofuel will have a difficult time competing.

The last part of this chapter considers the “final frontier” for genetic engineering: the ability to synthesize cell parts or even entire cells from scratch in the revolutionary new field of synthetic biology.

Check Your Understanding

- How has *Caldicellulosiruptor* been modified to produce ethanol directly from switchgrass?
- What are the advantages of using thermophiles to produce biofuels?
- What has been the limiting factor in engineering microalgae to produce greater amounts of lipids?

III • Synthetic Biology and Genome Editing

Scientists can stitch together bits and pieces of DNA from various sources to create artificial genes, operons, or entire genomes and can edit these new genetic constructs at will to change the properties of existing organisms or even to fabricate an entirely synthetic organism.

The term *synthetic biology* refers to the use of genetic engineering to create novel biological systems out of available biological parts, often taken from several different organisms. These biological parts (promoters, enhancers, operators, riboswitches, regulatory proteins, enzyme domains, signal receivers, etc.) have been termed *biobricks*. Synthetic biology links biobricks together in various combinations to form modules capable of generating complex behaviors (Figure 12.1). While we will discuss some amazing examples of synthetic biology (including the formation of synthetic cells) in Sections 12.11 and 12.12, college students are also trying their hand at synthetic biology. An undergraduate competition called the *International Genetically Engineered Machine* (iGEM; <https://igem.org/>) occurs annually worldwide. Teams in this competition have used synthetic biology to engineer products ranging from probiotic bacteria that secrete the anti-inflammatory cytokine interleukin-10 to help treat irritable bowel disease (cytokines and interleukins are discussed in Chapters 26 and 27), to microfluidic systems that “print” (assemble) genetic circuits and transform them into cells of *Escherichia coli*.

Direction of arrows indicates direction of transcription and color-coding is as indicated. H, *nifH*; D, *nifD*; K, *nifK*; Y, *nifY*; E, *nifE*. (b) Refactored “minimalist” nitrogen fixation pathway. RBS, ribosome-binding site. Data modified from Smanksi, M.J., Zhou, H., Claesen, J., Shen, B., Fischbach, M.A., and Voigt, C.A. 2016. *Nat. Rev. Microbiol.* 14, 135.

Another powerful new and rapidly developing technology allows the precise “editing” of genomes in living cells, a technique that has revolutionized biotechnology. In Section 12.13 we explore how the microbial immune system has been leveraged to edit any genome and the remarkable applications of this genome editing technology.

12.11 Synthetic Metabolic Pathways, Biosensors, and Genetic Circuits

A major focus of synthetic biology thus far has been the construction or modification of metabolic pathways. High-value products are often expensive because purifying them from their original source, typically plants, is costly. The pathways responsible for these products include proteins and RNAs that regulate the synthesis, export, and protection from harmful effects of the product. Thus the DNA encoding pathways for high-value products can range from 1000 to 100,000 base pairs of DNA, which makes it impossible to clone the necessary genes into a model system.

However, by using various enzyme and regulatory biobricks, synthetic biologists can reconstruct or *refactor* natural pathways into artificial ones that allow for easy expression in model systems. This refactoring ultimately leads to the efficient conversion of cheap and abundant substrates into high-value products. Figure 12.36 illustrates refactoring of the 20-gene pathway encoding nitrogen fixation (◀ Section 3.12) in *Klebsiella oxytoca*; the result is a streamlined and optimized five-gene pathway. While genetically modified organisms (GMOs) are used for refactoring and the production of high-value products, no foreign DNA is present in the products.

Engineering a Major Food Product

Vanillin, one of the most popular flavoring agents in the world, is a secondary metabolite extracted from the seedpods (vanilla beans) of orchids of the genus *Vanilla*. Natural vanillin is expensive because of the slow growth of orchids, their relatively low output, and the high production costs of cultivating and harvesting the beans. By analyzing the natural metabolic pathway for the production of vanillin, genetic engineers have synthesized strains of *Escherichia coli* and yeast that can synthesize the flavoring agent from glucose. Vanillin synthesis in *E. coli* requires five heterologously expressed enzymes, and once the necessary biobricks were incorporated into the bacterium, it produced vanillin identical in structure and taste to naturally produced vanillin. (However, some argue that naturally

produced vanilla contains additional compounds extracted from the vanilla beans that contribute to its unique taste.)

“Synbio vanillin,” as the *E. coli* product has been called, is commercially available as an inexpensive source of vanillin and has been used primarily for flavoring ice cream and baked goods. As the second most expensive spice in the world (behind saffron), natural vanilla is an especially costly ingredient for bulk use such as in ice cream. Synbio vanillin is a good example of how synthetic biology can be used to convert inexpensive feedstocks (corn sugar) into high-value products.

Synthetic Pharmaceuticals: Artemisinin and Malaria

Pharmaceuticals are often derived from natural products; aspirin, for example, was originally obtained from willow bark. While aspirin is now chemically synthesized, not all pharmaceuticals can be synthesized economically. One example is the antimalarial drug *artemisinin*. Malaria, which is caused by protozoans of the genus *Plasmodium*, is transmitted by mosquitoes and infects nearly 500 million people each year, primarily in tropical and subtropical countries (▶ Section 34.5). While various traditional antimalarials are in use, the parasite has evolved resistance to many of these and thus new antimalarial drugs are constantly needed. Artemisinin is an alternative antimalarial that is produced in limited amounts by the cultivated sweet wormwood plant *Artemisia annua*. To ensure availability of the drug, the *Semi-Synthetic Artemisinin Project* was initiated with the goal of engineering a microorganism for the synthesis of artemisinic acid, used for production of artemisinin (Figure 12.37).

A. annua naturally produces artemisinic acid by converting acetyl-CoA to farnesyl diphosphate (FPP; a 15-carbon intermediate) using the mevalonate biosynthetic pathway. FPP is then oxidized to artemisinic acid and dihydroartemisinic acid through an intermediate called *amorphaadiene*. Initially, the plan was to have *E. coli* produce artemisinic acid through fermentation. Synthetic biologists made numerous attempts to engineer *E. coli* with the correct biobricks to produce artemisinic acid through permutations of the natural pathway, inhibiting natural competing enzymes, mutating genes for codon optimization (Section 12.3), and modifying fermentation conditions, but no strategy emerged that could yield the amorphaadiene intermediate at sufficient levels. However, by transferring the necessary metabolic pathway biobricks to a modified strain of the baker's yeast *Saccharomyces cerevisiae* along with metabolic adjust-

Figure 12.37 Artemisinin synthesis through synthetic biology. A summary of the engineering steps used to modify a *Saccharomyces cerevisiae* yeast strain to produce artemisinic acid. Colored arrows represent expression of genes from the plant *Artemisia annua* and other genetic modifications.

ments to divert carbon flux toward the final product, synthetic biologists designed a yeast strain that produces large amounts of artemisinic acid that can then be chemically converted to artemisinin (Figure 12.37).

Synthetic biology has also been successful at synthesizing powerful painkilling drugs. For example, genetic engineers modified yeast to produce the chemical *thebaine*, a precursor to morphine and hydrocodone, from glucose. This was accomplished by the heterologous expression in yeast of 21 different genes that originated from sources as diverse as plants, a rat, and the gram-negative bacterium *Pseudomonas*. The synthesized thebaine can then be chemically converted to a suite of pain-relieving drugs and marketed by pharmaceutical companies.

Biosensors and Genetic Circuits: Photographic *Escherichia coli*

An early excursion into the world of synthetic biology was the use of genetically modified *E. coli* to produce photographs using light sensing and a *genetic circuit*, another name for a gene regulatory network. The engineered bacteria are grown as a lawn on agar plates, and when an image is projected onto the lawn, unilluminated bacteria make a dark pigment while illuminated bacteria do not. The result is a primitive photograph of the projected image (Figure 12.38).

Construction of the photographic *E. coli* required synthetic biologists to create three key biobricks to form a sensor linked to a genetic circuit: (1) a light sensor or detector and signaling module; (2) a pathway to convert heme (already present in *E. coli*) into the photoreceptor pigment phycocyanobilin (an accessory light-harvesting pigment of cyanobacteria, ► Section 14.4); and (3) an enzyme encoded by a gene whose transcription can be switched on and off to make the dark pigment (Figure 12.38a). The photoreceptor is a fusion protein (Section 12.5) in which the sensing half is the light-detecting part of the phytochrome protein from the cyanobacterium

Synechocystis. This required phycocyanobilin is not naturally made by *E. coli*; hence the need to install the biobrick that contained the pathway to make phycocyanobilin.

The other half of the fusion protein is the signal transmission domain of the EnvZ sensor protein from *E. coli*. EnvZ is part of a two-component regulatory system, its partner being OmpR (► Section 7.5). Normally, EnvZ activates the DNA-binding protein OmpR, and the latter in turn activates target genes by binding to the promoter. The hybrid protein was designed to activate OmpR in the dark but not in the light. This is because phosphorylation of OmpR is required for activation, and red light converts the sensor to a state in which phosphorylation is inhibited. Consequently, the target gene is *off* in the light and *on* in the dark. When a mask is placed over the Petri plate containing a lawn of the engineered *E. coli* cells (Figure 12.38b), cells in the dark make a pigment that cells in the light do not, and in this way a “photograph” of the masked image develops (Figure 12.38c).

The pigment made by the *E. coli* cells results from the activity of the lactose-degrading enzyme β -galactosidase, naturally present in *E. coli*. The target gene, *lacZ*, encodes this enzyme. In the dark, *lacZ* is expressed and β -galactosidase is made. The enzyme cleaves the lactose analog S-gal (3,4-cyclohexenoesucletin- β -D-galactopyranoside; similar to X-gal in Section 12.2) present in the growth medium to release galactose and a black dye. In the light, the *lacZ* gene is not expressed, no β -galactosidase is made, and so no dye is released. Contrast in the photograph is controlled by how much light cells see, which is governed by the nature of the mask that is used (Figure 12.38c).

Although bacterial photographs can hardly compare with digital photographs, the knowledge gained from assembling the biobricks required for bacterial photographs—work that is now many years old—helped form a foundation for the deployment of synthetic approaches in more complex biological systems, to which we turn now.

Figure 12.38 Bacterial photography. (a) Light-detecting *Escherichia coli* cells were genetically engineered using components from cyanobacteria and *E. coli* itself. Red light inhibits phosphate (P) transfer to the DNA-binding protein OmpR; phosphorylated OmpR is required to activate *lacZ* transcription (*lacZ* encodes β -galactosidase). (b) Procedure for making a bacterial photograph. The opaque portions of the mask correspond to zones where β -galactosidase is active and thus to the dark regions of the final image. (c) A bacterial photograph of a portrait of the eminent biologist Charles Darwin.

Biosensors and Genetic Circuits: Synchronized and Cyclical Drug Delivery

In Section 12.8 we discussed how features of the human microbiome (Chapter 24) can be used to deliver therapeutic agents to treat diseases including cancer. Synthetic biology is revolutionizing these treatment approaches through the design of synchronized genetic circuits that not only control the level of therapeutic delivery, but also the population level of the engineered microbe. We demonstrate this using the human pathogen *Salmonella enterica* (*typhimurium*), a bacterium that targets the gastrointestinal tract (► Section 33.10).

We have already seen how certain genetically modified gastrointestinal bacteria can grow and release anticancer drugs in the hypoxic environment of tumor cells (Section 12.8 and Figure 12.26a), and a similar anticancer strategy using *S. enterica* (*typhimurium*) has been developed. Advanced genetics can also be

performed on this bacterium, allowing for the strain to be manipulated not only to deliver drugs to tumors but to do so using an “internal clock.” To design a *S. enterica* (*typhimurium*) strain that releases an anticancer drug in a controlled and cyclical manner, genetic engineers took advantage of the natural ability of some microbes to communicate with others of their own kind through quorum sensing (◄ Section 7.7). Because a transcriptional activator (LuxR) is able to use the quorum-sensing molecule *N*-acyl homoserine lactone (AHL; ◄ Figure 7.18) as its inducer to activate transcription (◄ Section 7.3), a genetic circuit could be developed to link promoter regions of DNA that bind LuxR to genes that encode not only the production of AHL, but also the production of an anticancer drug and a cell lysis enzyme (Figure 12.39a). Because AHL can freely diffuse into and out of cells, this genetic circuit results in AHL levels accumulating as the cell density increases. As AHL levels increase, the inducer molecule binds to LuxR and this

Figure 12.39 Genetic circuits and synchronized therapeutic agents. (a) A tumor-targeting bacterial strain of *Salmonella* was modified to produce and sense the quorum-sensing molecule *N*-acyl homoserine lactone (AHL) in response to population increase. Because AHL diffuses freely in and out of cells (red arrows), the cellular concentration increases as the surrounding cell density increases. Increased AHL levels lead to production of a lysis protein (E), an anticancer drug, and more AHL due to their

corresponding genes being linked to a promoter that binds to the activator LuxR-AHL complex. This genetic circuit results in a positive feedback loop leading to cell lysis and drug release in the subpopulation of cells that encounter a specific threshold concentration of AHL. This cell lysis occurs in synchrony. Cells that did not encounter the required level of AHL survive to repopulate and initiate another cycle. (b) Time series of a coculture of *Salmonella enterica* (*typhimurium*) containing the part a genetic circuit, which is also

linked to GFP for visualization (bottom chamber of panel), and HeLa cancer cells (top chamber of panel). The panels show an increase in bacterial cell concentration (42 minutes) and lysis and cell death (180 minutes). Bacterial cell lysis and drug release coincide with HeLa cell death (white cells) at 180 minutes. Intact bacterial cells at 180 minutes are able to grow and reinitiate the time course cycle. HeLa cells are an immortal cell line used in medical research.

activator–inducer complex binds to the promoters of genes encoding four components: LuxI (AHL synthesis), the anticancer drug, a fluorescent protein (GFP) to monitor the dynamics of the circuit, and the lysis protein E from bacteriophage ϕ X174 (◀ Figure 11.6).

As the population of the engineered strain reaches a critical threshold, almost all cells in the population produce the components of the genetic circuit (Figure 12.39a). This leads to not only production of the anticancer drug, but also its release due to the production of the lysis E protein. However, a few outliers will exist in the population because of *phenotypic heterogeneity* (◀ Section 8.12), and these survivors will repopulate the tumor region (Figure 12.39a). The end result of this elegant genetic circuit is periodic bacterial lysis and drug delivery in response to a quorum-sensing clock.

Figure 12.39b illustrates the synchronized drug delivery circuit in action using a laboratory coculture system that allows cervical cancer HeLa cells to grow in a chamber above the engineered *S. enterica* (*typhimurium*) strain. The two cell types are separated and not allowed to mix, but molecules and drugs are able to move freely between the two growth chambers. As the engineered *S. enterica* (*typhimurium*) cell density increases, so does the level of GFP used to monitor the cells. This level of GFP decreases as the engineered microbes lyse from activation of the genetic circuit. Cell lysis leads to release of the anticancer drug and ultimately to HeLa cell death (Figure 12.39b).

By using biobricks encoding products and regulatory regions from various microorganisms, synthetic biology has produced a

synchronized and cyclical therapeutic agent. However, while modified, this engineered strain of *S. enterica* (*typhimurium*) still possesses most of its wild-type genome. We turn now to approaches to engineering cells with synthetic genomes.

12.12 Synthetic Cells

The synthesis of an entire cell from scratch can be considered the pinnacle of synthetic biology. This has not happened yet, but a related feat was announced in 2010: A group of scientists from the J. Craig Venter Institute (JCVI, California, USA) had produced a “synthetic” bacterium. However, the organism produced was not the result of assembling various biobricks to form a living organism—true *de novo* cell synthesis—but instead was the product of the artificial construction of a small bacterial genome from a known genome sequence and the insertion of this synthetic genome into a different bacterial species to yield viable cells (Figure 12.40).

Figure 12.40 Formation of a synthetic *Mycoplasma* cell. DNA fragments corresponding to the desired *Mycoplasma mycoides* chromosome are synthesized with overlapping ends (represented by the same colors). These DNA fragments are linked together using the homologous recombination machinery of *Saccharomyces cerevisiae*, with sites of homologous recombination indicated by lines. Once assembled, the synthetic chromosome is transformed into a cell of *Mycoplasma capricolum*. This results in a cell with two separate chromosomes. After cell division, one cell possesses the synthetic chromosome (considered the synthetic *M. mycoides*) and the other remains a wild-type *M. capricolum*. The cell containing the synthetic chromosome was identified because it contained the reporter gene *lacZ* and thus produced blue colonies (see Figure 12.10).

Construction of a synthetic cell was accomplished by synthesizing a 1.08-million-base-pair (Mbp) genome based on the known genome sequence of the bacterium *Mycoplasma mycoides*. This small circular chromosome was pieced together from linear fragments of DNA containing homologous ends and the homologous recombination complex of yeast cells. The fully assembled 901-gene synthetic chromosome was then purified and transformed into a cell of *Mycoplasma capricolum* (Figure 12.40). The synthetic chromosome contained a reporter gene, *lacZ*, absent from the *M. capricolum* genome, which caused colonies containing the synthetic chromosome to turn blue (see Figure 12.10); this was needed to distinguish *M. capricolum* cells containing the *M. mycoides* genome from those containing the *M. capricolum* genome after cell division (Figure 12.40). When cells in the blue colonies were examined, they showed all of the properties of the original *M. mycoides* cell. This new cell was named JCVI-syn1.0. Although JCVI-syn1.0 was not constructed solely from biobricks (the *M. capricolum* host cell contributed ribosomes, various enzymes, and other important cytoplasmic components), the experiment did prove that an entire genome could be transplanted from one species to another.

Since the original creation of JCVI-syn1.0, synthetic biologists have expanded their work to determining the minimal genome necessary for a free-living cell. Using comparative genomics and prior knowledge about specific gene sequences, microbiologists at JCVI designed and synthesized several minimal genomes that they hypothesized would sustain life. To their dismay, none of these resulted in a viable cell. So instead, they generated modules of DNA corresponding to a *Mycoplasma* genome and sewed different combinations together to form synthetic genomes. Once viable cells were obtained from transplanting these genomes as described above, nonessential genes from the smallest genome were identified by transposon mutagenesis. After removing these unnecessary genes, a synthetic minimal cell coined JCVI-syn3.0 was created (Figure 12.41). This autonomous life form possesses a 531-kilobase genome encoding just 473 genes; JCVI-syn3.0 thus contains a genome smaller than that of any other free-living cell.

Thomas Deerinck and Mark Ellisman

Figure 12.41 Synthetic biology and the design of a minimal cell. Scanning electron micrograph of cells of the autonomous strain JCVI-syn3.0 possessing a synthetic genome containing 473 genes.

While this work showcases the amazing advancements in synthetic biology and the potential for creating designer cells with novel functions, a surprising mystery surrounds this minimal cell: the roles for almost a third of JCVI-syn3.0's genes remain unknown, highlighting how much we still need to learn about the genetic foundation of a living cell.

- How were *Mycoplasma* transformants with the synthetic chromosome selected for?

12.13 Genome Editing and CRISPRs

In Chapter 9 we discussed clustered regularly interspaced short palindromic repeat (CRISPR) systems and their role in protecting *Bacteria* and *Archaea* from foreign DNA and maintaining genome integrity. Microbiologists studying a CRISPR system called *CRISPR/Cas9* (Cas9 refers to CRISPR associated protein 9) in the bacterium *Streptococcus pyogenes* discovered that the system could also recognize and cleave a specific DNA sequence within other cells and that foreign DNA could be inserted into the cut site. This discovery has revolutionized biology.

The CRISPR/Cas9 system provides the most powerful and precise tool yet for altering eukaryotic genomes in living cells. Indeed, *genome editing*, as it has come to be known, has been used successfully to edit the genomes of plants, animal embryos, and human cell lines. Here we explore how this system works, its benefits to synthetic biology, and how it can be used as a *gene drive* to propagate specific genes throughout a population of organisms.

Sequence Targeting by the Cas9 Protein

As was illustrated in Figure 9.37, CRISPR systems possess Cas proteins that function as endonucleases when guided to a piece of nucleic acid by the complementary binding of CRISPR RNAs (crRNAs). By designing a synthetic RNA molecule that both recruits the *Streptococcus* Cas9 protein and binds to the desired target DNA sequence, genetic engineers have harnessed the power of the CRISPR/Cas system to cut specific DNA sequences in the genome of virtually any cell. At the cut site, the DNA can either be ligated (yielding a gene deletion) or used for inserting new DNA (Figure 12.42a, b).

The synthetic RNA molecule used for gene editing is called a *synthetic guide RNA* (sgRNA), and Figure 12.42c shows a model of the Cas9 protein from *S. pyogenes* binding both the sgRNA and target DNA. For complete Cas9 endonuclease activity, a short *protospacer adjacent motif* (PAM; ◀ Figure 9.37) must also occur on the target DNA. Without this PAM sequence, the Cas9 protein will bind to the region where the sgRNA binds but will not cut. When the Cas9 protein does cut DNA, its two endonuclease domains (shown in purple in Figure 12.42c) cooperate to cut both DNA strands, and this generates double-stranded breaks (for simplicity, Figure 12.42a and b have single strands—shown as tubes—representing double strands). Depending on the target cell, various methods of delivering the CRISPR system can be used. Genes corresponding to the

targeted site of the genome. An sgRNA is synthesized to bind to a single target site on the genome through complementarity. This binding of the sgRNA to the DNA stimulates the Cas9 protein to cleave the

genome at the target site. Foreign DNA with ends homologous to the cleavage site can be incorporated into the cut site through homologous recombination. This results in a genomic insertion. (b) Deletion of a genomic region. Two separate target sites flanking the DNA to be deleted are selected. After the design, addition, and binding of sgRNAs corresponding to these regions, Cas9 protein-dependent DNA cleavage occurs. This results in a double-stranded break in the

(c)

target chromosome and a free piece of DNA. The double-strand break is then ligated by the cell's DNA double-strand break repair pathway, while the free piece of genomic DNA is degraded. This results in a genomic deletion. (c) Crystal structure of the *Streptococcus pyogenes* Cas9 protein. The target DNA is shown in green and the sgRNA in orange.

designed sgRNA and Cas9 protein are often cloned into a plasmid under regulatory control of a strong promoter. Alternatively, the sgRNA and mRNA corresponding to the Cas9 protein can be generated in vitro. In either case, the materials are injected directly into target cells to trigger the gene editing process.

The presence of a PAM sequence close to the desired cleavage site is often the only limitation to cutting a specific DNA sequence. However, the PAM sequence is just three nucleotides in length and thus occurs with frequency in most genomes. CRISPR systems from other bacteria also recognize different PAMs, so alternative Cas proteins may be employed if needed. To delete a region of DNA, two target cleavage sites flanking the DNA sequence to be deleted must be identified and corresponding sgRNAs designed (Figure 12.42b). By contrast, only one cleavage site and corresponding sgRNA are needed to insert DNA (Figure 12.42a). To edit a region of a chromosome, sgRNAs are designed to bind to target DNA. This binding stimulates the Cas9 protein to cleave the target site if a PAM sequence is nearby (Figure 12.42a, b).

While a Cas9 protein and sgRNA can be used to cut DNA at specific sites (Figure 12.42), how is new DNA *inserted* at the cleavage site and how does the DNA get ligated back together? These tasks are accomplished by harnessing the cell's own DNA repair machinery. If a piece of DNA containing sequences with homology to the cut site is added to the system, homologous recombination will be used to incorporate the DNA (◀ Section 9.5), yielding a genomic insertion (Figure 12.42a). If the goal is only to delete the chromosomal region between two cut sites, the nonhomologous double-strand DNA break repair pathway will be employed to ligate the DNA following the deletion event (Figure 12.42b). The mechanism used by this DNA repair pathway makes it possible for genetic engineers to create an insertion or a deletion of as few as one nucleotide in a gene sequence through the cleavage of a single target site. No additional piece of DNA is needed because one nucleotide is either added or removed during the re-ligation of the two strands of DNA.

CRISPR Editing in Practice

Applications of CRISPR genome editing have seen a meteoric rise since its discovery in 2013. By designing a Cas9-encoding gene to possess codons optimized for the organism of interest (Section 12.3) and engineering sgRNA to target the gene of interest, almost any organism's DNA can be edited. In fact, CRISPR gene editing has exploded in crop plants including rice, sorghum, wheat, corn, and soybeans. The CRISPR/Cas9 system has also been employed in tomato plants by targeting a gene region in which a mutation leads to leaves that are needle-like or wiry (Figure 12.43). In this study, DNA encoding the Cas9 protein and sgRNA was introduced into the plant cells using *Agrobacterium* and the Ti plasmid system (Figure 12.20). Because the resulting mutations are stable and heritable, CRISPR genome editing has also been used to engineer numerous beneficial vegetable and fruit modifications including drought-resistant lettuce, grapes with increased levels of vitamin C, and disease-resistant oranges.

While a Cas9 system has been used to excise the genome of the retrovirus HIV (the causative agent of AIDS, ◀ Section 11.11) from the genome of infected human cells in vitro, Cas proteins from other bacteria can be used to target HIV or other specific viral RNAs. These RNA-targeting Cas proteins have been harnessed to not only create highly sensitive and portable diagnostic tools for detecting viruses such as Zika (see Chapter 10 Explore the Microbial World, “DNA Sequencing in the Palm of Your Hand”), but also to target RNA viruses inside of cells. For example, the Csy4 CRISPR-associated protein from the bacterium *Pseudomonas* is an endoribonuclease that processes the long CRISPR transcript (◀ Figure 9.37). The Csy4 protein has been modified to recognize and destroy free HIV RNA in infected cells (Figure 12.44). Similarly, the CRISPR/Cas9 system from the bacterium *Francisella novicida* has been reprogrammed to target the single-stranded RNA genome of hepatitis C virus (a liver pathogen and a cause of liver cancer) in a human cell line.

Not only has CRISPR genome editing been used to delete, interrupt, and insert DNA sequences into a single location, it can also be used to target multiple genetic loci. An impressive example of this is the removal of 62 copies of the porcine endogenous retrovirus from swine cells. This retrovirus generates an immune response in humans and is one of the factors preventing the use of swine organs

Figure 12.44 CRISPR-mediated inhibition of HIV infection. The results of using the *Pseudomonas* Csy4 endoribonuclease CRISPR protein to target RNA-based HIV in infected human embryonic kidney cells. Red indicates HIV provirus integration into infected cells, while free HIV virions are indicated in green. Top panel: expression of an HIV–Csy4 targeting vector. Bottom panel: expression of a mutated vector containing a nonfunctional Csy4 protein. Adapted from Guo, R., H. Wang, J. Cui, G. Wang, W. Li, and J-F Hu. 2015. *PLoS ONE* 10(10): e0141335.

for transplants in humans (swine are anatomically very similar to humans). Although other swine proteins also induce an immune response in humans, genetic engineers predict that in the foreseeable future they will be able to edit away all of these factors to produce immune-friendly pig embryos for human organ production.

Currently, CRISPR genome editing appears to have very few limitations. In fact, fertility clinic human embryos that were nonviable and could not result in a live birth have even been modified. This landmark accomplishment and reports that scientists in China may have successfully created CRISPR-modified babies resistant to HIV, smallpox, and cholera have raised serious ethical questions regarding the use of CRISPR editing in humans. But the technique may be the key to eradicating a host of devastating genetic diseases before a baby carrying the genes for one or more of these diseases is born. However, more studies are needed to verify gene target specificity and the response of the human immune system to Cas proteins.

Gene Drives and Engineered Mosquitoes

Not only can Cas proteins be used to edit almost any gene, the system can also be used as a *gene drive* to spread specific mutations throughout entire populations over generations. Gene drives, which only occur in sexually reproducing organisms, result in an allele (different forms of a gene) being inherited more than the normal frequency of 50%. Gene drives do occur in nature, but they are often facilitated by selfish DNA such as transposons (◀ Section 9.11). Thus, the spread and chromosomal location of the mutation is difficult to control. By contrast, CRISPR and Cas9 gene editing allows for the inheritance of the allele to be specifically controlled. The spread of a specific allele is based on diploid organisms possessing two copies of most genes, the ability of the Cas9 protein to be targeted to a specific site by a synthetic guide RNA (sgRNA), the endonuclease activity of Cas9 resulting in double-stranded DNA breaks, and the homology-directed DNA repair pathway.

Figure 12.45*b* illustrates the spread of an allele through a mosquito population by normal Mendelian inheritance. By contrast, Figure 12.45*c* shows how linking genes for Cas9 and the sgRNA to

Figure 12.43 CRISPR editing of tomato genome. Interruption of the tomato *SIAG07* gene encoding an argonaute homolog results in plants that have wiry or spindly leaves (left) compared to a normal tomato plant (right).

Figure 12.45 Spread of gene drives by Cas9 technology. (a) The mosquito *Anopheles stephensi* containing a green fluorescent protein (GFP) allele linked to a Cas9 gene drive (left) compared to wild type (right). (b) Normal inheritance of an altered allele (in this example, the gene encoding GFP) in mosquitoes through Mendelian genetics. Mating of a modified insect with a wild-type insect results in a heterozygote

and only a 50% chance of the allele being transferred from parent to offspring. (c) By linking the allele to genes for Cas9 and synthetic guide RNA (sgRNA), the genetic modification in one copy of the chromosome spreads to a wild-type chromosome through the activity of Cas9 gene editing. The sgRNA guides the Cas9 endonuclease (solid red arrow) to cut the wild-type chromosome at a specific location, and the double-

strand break (dashed red arrow) results in DNA repair of the cut chromosome using the altered allele as a template for DNA replication. (d) The altered allele linked to the Cas9 system becomes a gene drive as its inheritance occurs over 50% of the time, which eventually leads to the genetic modification occurring in the entire population.

a specific allele results in movement of the allele from one chromosomal copy to the other. Once the cell expresses the Cas9 and sgRNA genes, the gene drive results in a double-stranded break in the wild-type chromosomal copy. This break in the DNA is lethal unless repaired by the homology-directed repair system, which works by copying DNA from the intact chromosome into the broken region. Thus, the Cas9-based gene drive ultimately results in the spread of the allele throughout the entire population as heterozygotes become homozygous for both the mutant allele and the Cas9 gene drive (Figure 12.45d).

The applications for gene drives are countless, but one that is showing promise for public health is the modification of mosquitoes. While Figure 12.45a shows a mosquito carrying a Cas9 gene drive linked to an allele for the green fluorescent protein (GFP) for easy visualization, gene drives are being developed to prevent mosquitoes from carrying diseases such as malaria. The system can also

be used to prevent the reproduction of disease-carrying mosquitoes by targeting an allele that results in female development. By linking this allele to a Cas9 gene drive, scientists have produced a population of mosquitoes unable to lay eggs after eight generations. While more scientific work is needed to determine the safety of releasing gene drives into nature, synthetic biologists now have the potential to eliminate malaria as a human disease and save millions of lives.

However, because the applications of gene drives are not just limited to pests like mosquitoes and have the potential to affect whole species, scientists have turned their attention to exploring ways to control the movement and reverse the activity of gene drives. Questions such as “Should scientists be altering genomes in ways that could have negative ecological consequences?” and “Can gene drives in one species be transmitted to other species?” are serious ones that need to be addressed. One way of protecting against these possibilities—effective biocontainment—is considered next to conclude this chapter.

Check Your Understanding

- What characteristics of the Cas9 protein make it an efficient DNA editing tool?
- What is the role of the sgRNA in genome editing? How is recombinant DNA inserted into a genome using CRISPR editing?
- Give an example of how a gene drive can slow or halt transmission of an infectious disease.

12.14 Biocontainment of Genetically Modified Organisms

Throughout this chapter we have focused on genetically engineering microbes as factories for the synthesis of high-value products, including specific enzyme systems for gene editing. While these applications of genetic engineering are clearly beneficial, environmental concerns remain that genetically modified organisms (GMOs) may spread their modified genes to wild-type populations with possible adverse consequences. Such concerns have slowed the acceptance of GMOs, and have been used to ban the sale of GMOs in certain countries. How can synthetic biology help solve these problems? Containment is one obvious answer and we consider this now.

Early Containment Schemes

Through the years, various schemes have been proposed for containing GMOs. For example, both the use of auxotrophic strains and the induction of genes encoding self-toxins have been attempted with GMOs, but for both strategies, successful and reliable implementation has been a problem. Recall that an auxotroph is a mutant derivative of a microbial species that has a nutritional requirement; without the nutrient, the auxotroph cannot grow (◀ Section 9.1). This dependency is the theory behind the proposal to use auxotrophs to contain GMOs. However, in nature, auxotrophic strains can often survive by cross-feeding off the metabolites of other organisms; in addition, the possibility always remains that an auxotrophic GMO could revert to the wild type by back mutation and lose its nutritional dependencies.

In Section 8.12 we saw how certain bacteria produce a growth-inhibiting toxin that slows cell growth to help ensure survival of the population under stressful conditions. This has also been explored as a mechanism for biocontainment. That is, if a GMO were to escape confinement within a bioreactor (where all growth conditions are ideal for production of the desired product), the toxin would kick in and trigger the dormant state, from which the escaped GMO could not recover. However, in nature, where a cell has to compete not only with cells of its own kind but also with other microbial species, survival strongly selects for toxin gene mutations; if such a mutation occurred quickly, the toxin system could be disarmed and the GMO might survive. Similarly to modifying bacteria for toxin production, a modified bacterial strain can be rewired to produce a lysis protein to control population levels, as we discussed in Section 12.11. However, a subset of cells will always be out of sync during expression of the lysis protein and persist to repopulate (Figure 12.39a).

Neither the auxotroph nor the toxin and lysis approaches adequately solve the problem of GMO containment. Moreover, none of these mechanisms address the possibility of engineered DNA being released through industrial waste streams and finding its way into other microorganisms by horizontal gene transfer (Chapter 9). Thus, to more

thoroughly and safely address the containment problem, genetic engineers have tapped into synthetic biology itself to devise novel methods of controlling GMOs in the environment, and we consider one now.

Rewiring the Genetic Code

A novel approach to prevent genetically modified bacteria from surviving outside of their bioreactor or other containment is to recode the genome of the GMO so the bacterium *can only grow if supplied with a synthetic amino acid* (Figure 12.46). This recoding results not only in biocontainment, but also in the ability to make novel proteins not found anywhere in nature. This requires rewiring the organism's genetic code and translational machinery (Chapter 6) to

Figure 12.46 Recoding and control of genetically modified *Escherichia coli*.

(a) The chromosome of an *E. coli* cell is genetically modified (recoded) to replace all TAG stop codons with TAA stop codons. The recoded *E. coli* stably maintains a vector expressing a tRNA with an AUC anticodon and an aminoacyl-tRNA synthetase (◀ Figure 6.32) that charges the tRNA with a synthetic amino acid (sAA). (b) Control of cell growth by inserting a UAG codon into mRNAs of essential proteins. If the synthetic amino acid is added to the growth medium, the recoded *E. coli* will translate functional essential proteins. If the synthetic amino acid is not present, an uncharged tRNA will bind to UAG codons engineered into essential proteins. This results in truncated essential proteins and ultimately cell death.

synthesize proteins containing the synthetic amino acid; a significant feat, but synthetic biology has already accomplished it.

In the first step of recoding a cell, scientists replaced all the TAG (UAG on the RNA) stop codons associated with open reading frames on the *Escherichia coli* chromosome with the TAA (UAA on the RNA) stop codon. They also deleted the gene for release factor 1 that terminates translation when the ribosome encounters a UAG on the mRNA. Because this manipulation placed an alternative stop codon at the end of genes that had TAG codons, proteins of the correct length are still produced during translation and the recoded cell grows normally. But this genetic manipulation also freed up the UAG stop codon to be reassigned another translational function.

To engineer dependence on a synthetic amino acid, genes for an aminoacyl-tRNA synthetase (◀ Section 6.8) that recognizes the synthetic amino acid (sAA) and a corresponding tRNA with an AUC anticodon were expressed from a vector (Figure 12.46a). This resulted in tRNAs with the AUC anticodon carrying the sAA. A set of essential genes was then modified to contain the TAG codon in positions where incorporation of the sAA would not affect protein activity. Thus for the recoded bacterium to translate mRNAs possessing the UAG codon, the cell must be fed the artificial amino acid (Figure 12.46a). If the growth environment does not have the sAA (as would be the case if the GMO escaped to nature), uncharged tRNAs will enter into the ribosome when a UAG codon is encountered; if this occurs during the translation of an essential protein, translation will stall and a truncated (and nonfunctional) protein will result (Figure 12.46b). This will lead to death of the cell and puts ultimate control of the recoded GMO into human hands. Because the TAG codon was placed in three essential genes, it is

extremely unlikely that sufficient mutations could arise to remove the GMO's dependence on the presence of the sAA.

While this strategy for biocontainment is dependent on the incorporation of the synthetic amino acid in regions of the protein that do not affect activity, synthetic biologists are using the same strategy to make proteins with novel activities and characteristics. By using amino acids with unique binding properties, there is no limit to the type of “alien” proteins that can be produced by synthetic biology. Some practical examples include modified drugs that are assimilated more easily or are less toxic, and improvements in the catalysis or specificity of enzymes for use in biotechnology. In addition to rewriting the genetic code, synthetic biology can also harness the CRISPR genome editing system to modify organisms to prevent their unwanted spread.

Continued advances in synthetic biology and the control of GMOs will not only allow for more widespread use of these organisms for synthesizing desired products and therapeutic agents in carefully controlled production settings but may also trigger the more extensive use of GMOs in general to solve urgent problems that remain in medicine, agriculture, and the environment.

Check Your Understanding

- Why is the use of auxotrophy not a good method for controlling the growth of a genetically modified organism?
- How can a tRNA be engineered to encode for a synthetic amino acid?
- Why is it unlikely that GMOs recoded to depend on a synthetic amino acid will mutate to no longer depend on the exogenously supplied synthetic amino acid?

CHAPTER REVIEW

I • Tools of the Genetic Engineer

- 12.1** The polymerase chain reaction is a procedure for amplifying DNA in vitro and employs heat-stable DNA polymerases. This amplified DNA is often used for cloning purposes and can be visualized by gel electrophoresis. Complementary nucleic acid sequences may be detected by hybridization.

Q How is DNA amplified in a polymerase chain reaction (PCR) procedure? Why do DNA polymerases from thermophilic microbes significantly improve the PCR procedure?

- 12.2** The isolation of a specific gene or region of a chromosome by molecular cloning is done using a cloning vector. Plasmids are useful cloning vectors because they are easy to isolate and purify and are often able to multiply to high copy numbers in bacterial cells. The choice of a cloning host depends on the final application. In many cases the host can be a bacterium, but in others, it is essential that the host be a eukaryote.

Q How does the insertional inactivation of β -galactosidase (LacZ) allow the presence of foreign DNA in a plasmid vector such as pUC19 to be detected?

- 12.3** Many cloned genes are not expressed efficiently in a foreign host. Expression vectors have been developed that both increase transcription of the cloned gene and control the level of transcription. To achieve very high levels of expression of eukaryotic genes in bacteria, the expressed gene must be free of introns. This can be accomplished by synthesizing cDNA from the mature mRNA encoding the protein of interest or by making an entirely synthetic gene. Protein fusions are often used to stabilize or solubilize the cloned protein.

Q What is the significance of reverse transcriptase in the cloning of animal genes for expression in bacteria?

- 12.4** Synthetic DNA molecules of desired sequence can be made in vitro and used to construct a mutated gene directly or to change specific base pairs within a gene by site-directed mutagenesis. Also, genes can be disrupted by inserting DNA fragments, called cassettes, into them, generating knockout mutants.

Q What does site-directed mutagenesis allow you to do that normal mutagenesis does not?

- 12.5** Reporter genes are genes whose products are easy to assay or detect. They are used to simplify and increase the speed of genetic analysis. In gene fusions, segments from two different genes, one of which is usually a reporter gene, are spliced together.

Q What is the key property of a reporter gene?

II • Making Products from Genetically Engineered Microbes: Biotechnology

- 12.6** The first human protein made commercially using engineered bacteria was human insulin. Recombinant bovine somatotropin is sometimes used in the United States to increase milk yield in dairy cows.

Q What classes of mammalian proteins are produced by biotechnology? How are the genes for such proteins obtained?

- 12.7** Genetic engineering can make plants resistant to disease and improve product quality. The Ti plasmid of the bacterium *Agrobacterium tumefaciens* can transfer DNA into plant cells. Genetically engineered commercial plants are called genetically modified organisms (GMOs).

Q What is the Ti plasmid and how has it been of use in genetic engineering?

- 12.8** Many recombinant vaccines have been produced or are under development. These include live recombinant, vector, and subunit vaccines. Properties associated with pathogens can be used to develop cancer-treating therapeutic agents.

Q What is a subunit vaccine and why are subunit vaccines considered a safer way of conferring immunity to viral pathogens than attenuated virus vaccines?

- 12.9** Genes for useful products may be cloned directly from DNA or RNA in environmental samples without first isolating the organisms that carry them. In pathway engineering, genes that encode the enzymes for a metabolic pathway are assembled. These genes may come from one or more organisms, but the engineering must achieve regulation of the coordinated sequence of expression required in the pathway.

Q How has metagenomics improved the discovery of novel useful products in biotechnology?

- 12.10** While select microorganisms can produce biofuels in small amounts, others can be modified to produce various

biofuels through pathway engineering. This modification often requires genes from multiple microorganisms. New tools for genetically manipulating microalgae have also been developed to facilitate biofuel production.

Q How can biodiesel be produced from microalgae-biosynthesis products?

III • Synthetic Biology and Genome Editing

- 12.11** Instead of modifying or improving a single existing pathway, synthetic biology focuses on engineering novel biological systems by linking known biological components together in various combinations. These modifications can result in the production of high-value products and synchronized biofactories.

Q How does synthetic biology differ from engineering of *Escherichia coli* to produce indigo?

- 12.12** Through the use of recombineering techniques, linear fragments of DNA can be synthesized and assembled into a genome. These synthesized genomes can then be transplanted into bacterial cells, displacing the parent genome and thus creating a synthetic cell.

Q How has the creation of a synthetic cell allowed microbiologists to probe the minimal genome required for autonomous life?

- 12.13** Not only can CRISPR systems be used as a prokaryotic immune system, they can also be modified to edit the genomes of eukaryotes. CRISPR requires a guide RNA to locate the genes to be cut and Cas proteins to cut the DNA. The resulting double-stranded breaks are suitable for the insertion of foreign DNA.

Q How has CRISPR editing technology been applied to targeting virus-infected eukaryotic cells?

- 12.14** With the advancements in genetic engineering, methods for controlling genetically modified organisms are imperative. One promising method is the use of synthetic biology to recode organisms for dependence on the presence of synthetic amino acids.

Q What are some mechanisms for controlling a genetically modified organism other than making it dependent on synthetic amino acids?

APPLICATION QUESTIONS

- Suppose you have just determined the DNA base sequence for an especially strong promoter in *Escherichia coli* and you are interested in incorporating this sequence into an expression vector. What steps would you take and which tools would you use to be sure that this promoter actually worked as expected in its new location?
- You have just discovered a protein in mice that may be an effective cure for cancer, but it is present only in tiny amounts. Describe the steps you would use to produce this protein in therapeutic amounts. Which host would you want to clone the gene into and why? Which host would you use to express the protein in and why?

3. Describe how you could use a soil sample and metagenomics to isolate a new antifungal protein that protects wheat from fungal infection. What steps could you take in the laboratory to modify this antifungal protein to be more effective against a broad range of fungal plant pathogens? Suppose you want to create genetically modified wheat that expresses your improved antifungal protein; what general steps would you take to introduce the foreign gene using CRISPR technology?
4. Describe how you could recode *Escherichia coli* to produce novel proteins containing more than the standard 22 amino acids.

CHAPTER GLOSSARY

Attenuate to decrease or eliminate the virulence of a pathogen or virus

Bacterial artificial chromosome (BAC) a circular artificial chromosome with a bacterial origin of replication

Biotechnology the use of organisms, typically genetically altered, in industrial, medical, or agricultural applications

Cassette mutagenesis creating mutations by the insertion of a DNA cassette

Complementary DNA (cDNA) DNA made from an RNA template during the reverse transcription PCR (RT-PCR) procedure

DNA cassette an artificially designed segment of DNA that usually carries a gene for resistance to an antibiotic or some other convenient marker and is flanked by convenient restriction sites

Expression vector a cloning vector that contains the necessary regulatory sequences to allow transcription and translation of cloned genes

Gel electrophoresis a technique for separation of nucleic acid molecules by passing an electric current through a gel made of agarose or polyacrylamide

Gene disruption (also called gene knockout) the inactivation of a gene by insertion of a DNA fragment that interrupts the coding sequence

Gene fusion a structure created by joining together segments of two separate genes, in particular when the regulatory region of one gene is joined to the coding region of a reporter gene

Genetically modified organism (GMO) an organism whose genome has been altered using genetic engineering; the abbreviation GM is also used in terms such as GM crops and GM foods

Genetic engineering the use of in vitro techniques in the isolation, alteration, and expression of DNA or RNA and in the

development of genetically modified organisms

Green fluorescent protein (GFP) a protein that fluoresces green and is widely used in genetic analysis

Heterologous expression the transcription and translation of a gene or genes from one organism in a different organism

Hybridization the joining of two single-stranded nucleic acid molecules by complementary base pairing to form a double-stranded hybrid DNA or DNA–RNA molecule

Molecular cloning the isolation and incorporation of a fragment of DNA into a vector where it can be replicated

Northern blot a hybridization procedure where RNA is the target and DNA or RNA is the probe

Nucleic acid probe a strand of nucleic acid that can be labeled and used to hybridize to a complementary molecule from a mixture of other nucleic acids

Operon fusion a gene fusion in which a coding sequence that retains its own translational signals is fused to the transcriptional signals of another gene

Pathway engineering the assembly of a new or improved biochemical pathway using genes from one or more organisms

Polymerase chain reaction (PCR) the artificial amplification of a DNA sequence by repeated cycles of strand separation and replication

Polyvalent vaccine a vaccine that immunizes against more than one disease

Protein fusion a gene fusion in which two coding sequences are fused so that they share the same transcriptional and translational start sites

Recombinant DNA a DNA molecule containing DNA originating from two or more sources

Reporter gene a gene used in genetic analysis because the product it encodes is easy to detect

Restriction enzyme an enzyme that recognizes a specific DNA sequence and then cuts the DNA; also known as a restriction endonuclease

Shuttle vector a cloning vector that can replicate in two different organisms; used for moving DNA between unrelated organisms

Site-directed mutagenesis the construction in vitro of a gene with a specific mutation

Southern blot a hybridization procedure where DNA is the target and RNA or DNA is the probe

Subunit vaccine a vaccine that contains only a specific protein or two from a pathogen

Synthetic biology arranging biobricks to form new genetic elements for insertion into microbes or higher organisms

T-DNA the segment of the *Agrobacterium tumefaciens* Ti plasmid that is transferred into plant cells

Ti plasmid a conjugative plasmid in the bacterium *Agrobacterium tumefaciens* that can transfer genes into plants

Transgenic organism a plant or an animal with foreign DNA inserted into its genome

Vector (as in cloning vector) a DNA molecule that is replicated by a host cell and used to carry cloned genes or other DNA segments for genetic engineering

Vector vaccine a vaccine made by inserting genes from a pathogenic virus into a relatively harmless carrier virus

Yeast artificial chromosome (YAC) an artificial chromosome with a yeast origin of replication and a centromere sequence

Exploring Viral Genesis

Unlike cells, viruses cannot perform metabolic reactions or conserve energy, yet viruses thrive in a world filled with cells. Viruses can evolve with frightening speed, and a tremendous diversity of viruses exist. Indeed, it is likely that every cellular organism can be a host for several different viruses.

While we have learned much about viruses, we know little about their evolution. Most viral genomes have few genes—indeed, the smallest have as few as three—and as a result, it is difficult to reconstruct the evolutionary history of all viruses as has been done for cells. Hence, we can only speculate about viral origins. All viruses might have diverged from one ancestral virus that appeared soon after the origin of cellular life, some 3.8 to 4.3 billion years ago. However, another possibility is that viruses have multiple origins, appearing spontaneously again and again over the history of life.

To address these hypotheses, we must understand mechanisms that promote viral genesis. One important step in viral genesis is the origin of the viral capsid. All capsids are

formed by self-assembly of one or a few proteins into a hollow molecular structure. Similar structures already exist in cells. For example, consider flagella and carboxysomes; both are hollow structures formed by self-assembling proteins. Another example is the enzyme lumazine synthase produced by the bacterium *Aquifex aeolicus*. Copies of this protein spontaneously assemble into capsid-like protein shells, and, with a few simple modifications in the laboratory, can be altered to package their own mRNA, resulting in virus-like nucleocapsids containing an RNA genome (see photo, capsids are 31 nm in diameter).

This discovery suggests that it could be surprisingly easy for viruses to originate spontaneously by mutation of cellular proteins that captured bits of nucleic acid. Thus, it is indeed possible that the viral diversity we observe today has many different origins.

I • Early Earth and the Origin and Diversification of Life

Microbes first appeared on Earth about 4 billion years ago and proceeded to colonize every habitable environment and oxygenate the planet. Cells of *Bacteria* and *Archaea* combined in some way to give rise to eukaryotic cells, and the evolutionary path that all cells have traveled is recorded in the nucleotide sequences of their DNA.

Evolution is a process that unifies all branches of biology because all living things undergo change over time and all have descended from the same universal ancestor. In this chapter, we tackle the topic of microbial evolution and describe methods for unraveling evolutionary relationships between microorganisms. We will also see how microbial evolution informs microbial systematics, a system we will use to describe relationships among microorganisms as we explore the diversity of the microbial world in the following five chapters.

In these first sections, we consider the possible conditions under which life arose, the earliest evidence for cellular life, and its divergence into three evolutionary lineages: *Bacteria*, *Archaea*, and *Eukarya*. Although much about these events and processes remains speculative, geological and molecular evidence has combined to build a plausible scenario for the earliest events in the **evolution** of life and for the fundamental impacts that microbes have had on the history of our Earth.

13.1 Formation and Early History of Earth

The Earth of 4 billion years ago (bya) would be foreign and inhospitable to human eyes, but this sterile wasteland of blasted rock and boiling seas was the incubator from which all life sprang. Since few fossils exist to tell the story of the early Earth, most of what we know is inferred from chemical and isotopic analyses of ancient rocks and minerals. However, we will see in this chapter that we can infer ancient evolutionary events from living organisms by comparing their molecular structures and sequences to determine their common history of descent. The story of life begins not long after the dawn of our solar system with the formation of Earth itself.

Origin of Earth

Earth formed about 4.5 bya (**Figure 13.1**), based on analyses of slowly decaying radioactive isotopes. Our planet and the other planets of our solar system arose from materials making up a disk-shaped nebular cloud of dust and gases released by the supernova of a massive old star. As a new star—our sun—formed within this cloud, it began to compact, undergo nuclear fusion, and release large amounts of energy in the form of heat and light. Materials left in the nebular cloud began to clump and fuse due to collisions and gravitational attraction, forming tiny aggregates that gradually grew larger to form clumps that eventually coalesced into planets. Energy released in this process heated the emerging Earth as it formed, as did energy released by radioactive decay within the condensing materials, forming a planet Earth of fiery hot magma. As Earth cooled over time, a metallic core, rocky mantle, and a lower-density, thin surface crust formed.

The inhospitable conditions of early Earth, characterized by a molten surface under intense bombardment by asteroids and other objects from space, persisted for up to 500 million years. The intense heat and the absence of liquid water indicate that early Earth was completely devoid of life. Furthermore, the early Earth was anoxic, and the absence of O₂ means that Earth lacked an ozone layer, allowing intense ultraviolet (UV) light to sterilize its surface. Water on Earth originated from volcanic outgassing of the planet's interior and from innumerable collisions with icy comets and asteroids. Given Earth's heat at the time, this water would have been present only as water vapor. No rocks dating to the origin of Earth have yet been discovered, presumably because they have undergone geological metamorphosis. However, ancient crystals of the mineral zircon (ZrSiO₄) have been discovered that were formed on the early Earth, and these materials have given us a glimpse of conditions on Earth prior to the origin of life.

Figure 13.1 Major landmarks in biological evolution, Earth's changing atmospheric chemistry, and microbial metabolic diversification. The oldest date for the origin of life is fixed by the time of Earth's origin, and the minimum time for the origin of oxygenic photosynthesis is fixed by the Great Oxidation Event, about 2.4 billion years ago (bya). Note how the oxygenation of the atmosphere from cyanobacterial metabolism was a gradual process, occurring over a period of about 2 billion years. Compare this figure with the introduction to the antiquity of life on Earth shown in Figure 1.10.

Liquid water is a requirement for life, and its eventual presence on Earth made possible the origin of life. Analyses of ancient zircon crystals, including impurities trapped in these crystals and their oxygen isotope ratios (we discuss the use of isotopic analyses as indications of living processes in Section 19.10), provide evidence for a solid crust and liquid water on Earth as early as 4.3 bya (Figure 13.1). Additional evidence of water comes from ancient sedimentary rocks, since sedimentary rocks are only formed under water. Among the oldest surviving sedimentary rocks are those found in southwestern Greenland, dating to 3.86 bya. These ancient rocks indicate the presence of early oceans. These rocks also contain the fossilized remains of cells (Figure 13.2), as well as carbon isotope ratios that provide evidence for life. Furthermore, graphite inclusions having carbon isotope ratios of biogenic origin are found in zircon minerals that are between 3.7 and 4.1 bya. These lines of evidence show that liquid water appeared prior to 4 bya and soon thereafter the first life forms appeared.

Origin of Cellular Life

The origin of life on Earth remains the greatest of mysteries, obscured by the depths of time. Few rocks survive unaltered to testify about this period of Earth's history. Experimental evidence indicates that organic molecules such as RNA nucleotides, amino acids, and lipids can form spontaneously under conditions that were present on the early Earth, providing the preconditions needed for the first living systems. However, conditions on Earth's surface more than 4.1 bya, in particular the extremely hot temperatures

and high levels of ultraviolet radiation, were likely hostile to the origin of life as we know it.

One hypothesis holds that life may have originated at hydrothermal systems on the ocean floor (Figure 13.3). Deep on the ocean floor, protected from the lethal UV radiation at Earth's surface, conditions would have been less hostile and more stable than on land. A steady and abundant supply of energy in the form of reduced

Figure 13.3 Submarine mounds and their possible link to the origin of life. Deep-sea hydrothermal vents are a likely site for the origin of life on Earth. They are stable environments conducive to life and they provide a source of chemical energy, precursors required for the formation of biological molecules, and mineral pores that can serve as compartments to

house pre-cellular biochemical reactions. (a) Precursor molecules form abiotically and accumulate within mineral pores. (b) Chemical gradients that form within mineral pores provide a source of energy that drives the replication of pre-cellular biological molecules. (c) Membranes eventually take over the role of mineral compartments, leading to the formation of the

first cells. (d) Photo of an actual hydrothermal mound. Hot, mineral-rich hydrothermal fluid mixes with cooler, more oxidized ocean water, forming precipitates of Fe and S compounds, clays, silicates, and carbonates. These mineral precipitates form pores that could have served as energy-rich compartments to facilitate the evolution of pre-cellular forms of life.

inorganic compounds—hydrogen (H₂), hydrogen sulfide (H₂S), and elemental sulfur (S⁰), for example—would have been available at these hydrothermal systems. The unique geochemistry of these sites can support the abiotic production of molecules critical for the emergence of life, such as amino acids, lipids, sugars, and nucleotides. Furthermore, minerals that form in these systems can produce compartmentalized structures that may have been necessary for conserving energy prior to the emergence of biological membranes. Whether on the seafloor or elsewhere, some form of prebiotic chemistry must have facilitated the development of the first self-replicating systems, the precursors to cellular life.

Molecules of RNA were likely a central component of the first self-replicating systems, and it is possible that life began in an RNA (rather than DNA) world (Figure 13.4). RNA molecules can perform diverse biochemical functions. For example, RNA molecules are the backbone of certain molecules essential to all cells, such as ATP (used in energy transfer), NADH (used in electron transfer), and coenzyme A (used in many biosynthetic reactions) (Chapter 3). RNA can also bind small molecules (such as nucleotides and amino acids), can catalyze certain simple biochemical reactions, and can be the template for its own synthesis. In addition, RNA is able to catalyze protein synthesis through the activities of ribosomal RNAs, tRNAs, and mRNAs (◀ Section 6.10). Hence, it is not unreasonable to imagine that the earliest forms of life relied exclusively on RNAs and had little or no need for DNA or proteins.

Eventually, however, proteins synthesized by RNA molecules replaced the catalytic role of RNAs in primitive cells (proteins can catalyze many reactions that RNA cannot) and at some later point, DNA, a molecule that is inherently more stable than RNA and

therefore a better repository of genetic (coding) information, assumed the role of the genome and became the template for RNA synthesis (Figure 13.4). The earliest cellular forms of life likely possessed elements of this three-part system of DNA, RNA, and protein, in addition to a membrane system capable of conserving energy and preventing cell leakage. The *last universal common ancestor* (LUCA) of all extant life likely existed at 3.8–3.7 bya, the point at which *Bacteria* and *Archaea* diverged and life began to diversify into the cellular forms we would recognize today.

The Last Universal Common Ancestor

Following the origin of cells, microbial life likely experienced a long period of metabolic diversification, exploiting the various energy resources available on Earth. For much of Earth’s history the planet, including all of its oceans, was anoxic (Figure 13.1). Thus, the energy-generating metabolism of primitive cells would have been exclusively *anaerobic*. Furthermore, organic matter was largely absent and so early cells must have been chemolithotrophic, using substances such as H₂ and H₂S spewed out of volcanoes and thermal springs as electron donors. H₂ is also produced abiotically when pyrrhotite (FeS), an abundant volcanic mineral on the early earth, reacts with H₂S to yield pyrite (FeS₂) and H₂. Regardless of the source of H₂, this simple molecule is thought to have been the basis of a primitive energy metabolism based on the proton motive force (Figure 13.5). Elemental sulfur (S⁰), also abundant on the early Earth, was likely one of the first acceptors of electrons from H₂ oxidation; the reduction of S⁰ to yield H₂S is exergonic and can be accomplished by a single enzyme (Figure 13.5). Because organic carbon

UNIT
3

Figure 13.4 Events hypothesized to precede the origin of cellular life. The earliest self-replicating biological systems may have been based on catalytic RNA. At some point RNA enzymes evolved the capability to synthesize proteins, and proteins became the main catalytic molecules. Conversion from RNA- to DNA-based genomes required the evolution of DNA and of RNA polymerases. The lipid bilayer is the site of electron transport, and the evolution of this structure was likely important for energy conservation, in addition to containing and protecting biomolecules. The last universal common ancestor (LUCA), which preceded the divergence of *Bacteria* and *Archaea* (see Figure 13.9), was a cellular organism that had a lipid bilayer and used DNA, RNA, and protein. Horizontal gene transfer (HGT) may have allowed rapid transfer of beneficial genes among early forms of life.

Figure 13.5 A possible energy-conserving scheme for primitive cells. The earliest cells could have generated energy by using H_2 as electron donor and S^0 as electron acceptor, both of which are abundant in hydrothermal systems and are also emitted from volcanoes. H_2 can also be formed from an abiotic reaction between FeS and H_2S , both of which were common on the early Earth. Such reactions could have allowed early cells to colonize diverse habitats.

was scarce on the early Earth, these primitive chemolithotrophs likely used CO_2 and N_2 as major sources of C and N for biosynthesis (see autotrophy and nitrogen fixation, Chapter 3).

By analyzing the gene content of genomes from living organisms across the tree of life, we can identify those genes that were most likely present in the earliest cells. A total of just 355 genes trace back to the last universal ancestor. These genes indicate that LUCA was an anaerobic organism that lived in a high-temperature environment rich in sulfur and iron and used H_2 as a source of energy and CO_2 as a source of carbon. These traits suggest that LUCA could have lived in a hydrothermal environment (Figure 13.3). Unsurprisingly, these cells had all the genetic machinery required for DNA replication, transcription, and translation, as well as ATP synthase. These early cells had the capacity to metabolize H_2 and CO_2 , likely producing either acetate (acetogens, ► Section 14.14) or methane (methanogens, ► Section 14.15) as their waste products. These early forms of chemolithotrophic metabolism along with the reduction of S^0 (Figure 13.5), all driven by H_2 as electron donor, would likely have supported the production of large amounts of organic compounds from autotrophic CO_2 fixation. Over time, these organic materials would have accumulated and provided the conditions needed for the evolution of chemoorganotrophic bacteria with diverse metabolic strategies to conserve energy from the oxidation of organic compounds.

Eventually Earth became a highly oxic planet, with an atmosphere containing the high levels of O_2 that we breathe today (Figure 13.1). Microbes catalyzed this key geochemical transition in Earth's history, and we explore this topic now.

Check Your Understanding

- What characteristics would have made the surface of Earth inhospitable to the formation of life 4.5 billion years ago?
- How do we know when oceans were first present on Earth? Why is the presence of oceans significant to the origins and diversification of life?
- What lines of reasoning support the hypothesis that the first self-replicating systems were based on RNA molecules?

13.2 Photosynthesis and the Oxidation of Earth

The evolution of photosynthesis was a biological breakthrough that radically changed the chemistry of Earth. Phototrophic organisms use energy from the sun to oxidize molecules such as H_2S , S^0 , Fe^{2+} , or H_2O and to synthesize complex organic molecules from carbon dioxide or simple organic molecules (► Sections 14.2 and 14.3). Over time, the products of photosynthesis accumulated in the biosphere, stimulating the further diversification of microbial life. Earth's first phototrophs were anoxygenic (cells that do not produce O_2 , ► Sections 14.5 and 15.4–15.7), but from these evolved the *Cyanobacteria*, the earliest O_2 -producing (oxygenic) phototrophs (Figure 13.1, ► Section 15.3).

Fossilized microbial formations called **stromatolites** can be found in rocks that are 3.5 bya, providing some of the earliest conclusive evidence of life on Earth (Figure 13.6). Stromatolites, or “layered rocks,” are formed when microbes cause the deposition of carbonate or silicate minerals that promote fossilization (we discuss microbial mats in ► Section 20.5). Stromatolites were diverse and common on Earth between 2.8 and 1 bya but declined dramatically in abundance over

Figure 13.6 Ancient and modern stromatolites. (a) The oldest known stromatolite, found in a rock about 3.5 billion years old from the Warrawoona Group in Western Australia. Shown is a vertical section through the laminated structure preserved in the rock. Arrows point to the laminated layers. (b) Stromatolites of conical shape from 1.6-billion-year-old dolomite rock from northern Australia. (c) Modern stromatolites, Darby Island, Bahamas. The large stromatolite in the foreground is about 1 m in diameter. (d) Modern stromatolites composed of thermophilic cyanobacteria growing in a thermal pool in Yellowstone National Park, USA. Each structure is about 2 cm high. (e) Modern stromatolites from Shark Bay, Australia. Individual structures are 0.5–1 m in diameter.

the last billion years. Stromatolites are largely gone from Earth today, and yet modern examples of this ancient microbial ecosystem can still be found in certain shallow marine basins (Figure 13.6c, e) or in hot springs (Figure 13.6d). Phototrophic bacteria, such as cyanobacteria (► Section 15.3) and anoxygenic phototrophs, play a central role in the formation of modern stromatolites. Ancient stromatolites contain microfossils that appear remarkably similar to modern species of phototrophic bacteria (Figure 13.7a). Hence, the earliest phototrophic organisms may have evolved in the *Bacteria* more than 3.5 bya, giving rise to the stromatolites we observe in the fossil record.

The first phototrophs were anoxygenic and likely used H_2S as electron donor for CO_2 fixation, generating elemental sulfur (S^0) as a waste product (► Section 14.5). How could the first phototrophs have evolved at a time when life existed mostly near hydrothermal systems? A clue came from the recent discovery of anoxygenic phototrophs living at hydrothermal vents in the complete darkness of the deep ocean. These phototrophs actually carry out photosynthesis using infrared radiation generated by the heat of hydrothermal vents. Likewise, the first photosynthetic organisms likely lived in the dark, at hydrothermal vents where H_2S and infrared radiation were abundant. Diversification of anoxygenic phototrophs led to species that were able to use a range of electron donors including Fe^{2+} , which was abundant throughout Earth's early oceans. The ability to use Fe^{2+} as an electron donor likely allowed early phototrophs to escape from hydrothermal systems and colonize shallow regions of

Earth's early oceans where light was abundant but where overlying water still provided protection from UV radiation.

The ability to use solar radiation as an energy source allowed phototrophs to diversify extensively. By 2.5–3.3 bya, the cyanobacterial lineage evolved a photosystem capable of oxygenic photosynthesis (► Section 14.6) in which H_2O supplanted H_2S as the reductant for CO_2 , thereby generating O_2 as a waste product. About a billion years later, eukaryotic oxygenic phototrophs appeared and can be seen in the microfossil record (Figure 13.7b). The origin of oxygenic photosynthesis and the rise of O_2 in Earth's atmosphere (Figure 13.1) caused the greatest change ever in the history of our biosphere and set the stage for the evolution of even newer and more complex forms of life that evolved to exploit the energy available from O_2 respiration. We look at the evidence for and consequences of Earth's oxidative transformation now.

The Rise of Oxygen: Banded Iron Formations

In the absence of O_2 , most of Earth's iron would have been present in reduced forms (Fe^0 and Fe^{2+}), and large amounts of iron were dissolved in Earth's anoxic oceans. Molecular and chemical evidence indicates that oxygenic photosynthesis first appeared on Earth several hundred million years before significant levels of O_2 appeared in the atmosphere. However, the O_2 that cyanobacteria produced could not accumulate in the atmosphere because it reacted spontaneously with the reduced iron minerals in the oceans to make iron oxides. By 2.4 bya, O_2 levels had risen to one part per million, a tiny amount by present-day standards, but enough to initiate what has come to be called the *Great Oxidation Event* (Figure 13.1).

The metabolism of cyanobacteria yielded O_2 that oxidized reduced minerals containing Fe^{2+} to iron oxides containing Fe^{3+} . These iron oxide minerals became a prominent marker in the geological record. Iron oxides are poorly soluble in water and would have precipitated in the oceans, raining down onto the seafloor and forming sedimentary structures we see today as **banded iron formations** (Figure 13.8), laminated sedimentary rocks formed in deposits of iron- and silica-rich materials. In addition to cyanobacteria, anoxygenic phototrophs that oxidize Fe^{2+} likewise contributed to the formation of these banded iron formations. Much of the iron in rocks of Precambrian origin (>0.5 bya, see Figure 13.1) exists in banded iron formations, and today these minerals are mined as a major source of iron ore. During this span of Earth history, lasting more than 1.5 billion years, the presence of precipitating iron minerals could have caused the oceans to appear brown, or black, or even red rather than the blue color we know today. Only after the abundant Fe^{2+} on Earth was oxidized could O_2 begin to accumulate in the atmosphere, and not until 600–900 million years ago did atmospheric O_2 reach present-day levels (~21%, Figure 13.1).

As O_2 accumulated on Earth, the atmosphere gradually changed from anoxic to oxic. Species of *Bacteria* and *Archaea* unable to adapt to this change were increasingly restricted to anoxic habitats because of the toxicity of O_2 and because it chemically oxidized the reduced substances upon which their metabolisms depend. However, the oxic atmosphere also created conditions for the evolution of various new metabolic schemes, such as sulfide oxidation, nitrification, and the various other aerobic chemolithotrophic processes described in Chapter 14. Microbes that evolved the capacity to respire O_2 gained

Figure 13.7 More recent fossil bacteria and eukaryotes. (a) One-billion-year-old microfossils from central Australia that resemble modern filamentous cyanobacteria. Cell diameters, 5–7 μm . (b) Microfossils of eukaryotic cells from the same rock formation. The cellular structure is similar to that of certain modern green algae, such as *Chlorella* species. Cell diameter, about 15 μm . Color was added to make cell form more apparent.

Figure 13.8 Banded iron formations. An exposed cliff made of sedimentary rock about 10 m in height in Western Australia contains layers of iron oxides (arrows) interspersed with layers containing iron silicates and other silica materials. The iron oxides contain ferric iron (Fe^{3+}) produced from ferrous iron (Fe^{2+}) primarily by the oxygen released by cyanobacterial photosynthesis.

a tremendous energetic advantage because of the high reduction potential of the $\text{O}_2/\text{H}_2\text{O}$ couple (◀ Section 3.2 and Figure 3.4), and with more energy at their disposal, aerobes could reproduce far more rapidly than anaerobes.

The Ozone Shield

An important consequence of O_2 for the evolution of life was the formation of *ozone* (O_3). The sun bathes Earth in intense amounts of ultraviolet (UV) radiation, which is lethal to cells and can cause severe DNA damage (◀ Section 9.4). When O_2 is subject to UV radiation from the sun, it is converted to ozone, which strongly absorbs UV radiation in wavelengths up to 300 nm. The conversion of O_2 to O_3 creates an *ozone shield*, a barrier that protects the surface of Earth from much of the UV radiation from the sun. Prior to the generation of the ozone shield, the punishing UV irradiation from the sun would have made Earth's surface fairly inhospitable for life, restricting life to environments that provided protection from UV radiation, such as in the oceans or in the subsurface. However, as Earth developed an ozone shield, organisms could range over the terrestrial surface of Earth, exploiting new habitats and evolving ever-greater diversity. Figure 13.1 summarizes some landmarks in biological evolution and Earth's atmospheric chemistry as Earth transitioned from an anoxic to a highly oxic planet.

Microscopic examination of ancient rocks has revealed timelines for the origin of life and major changes in Earth's geochemistry. But what about modern organisms—how can we unravel their evolutionary relationships? We consider next how this is possible.

Check Your Understanding

- Why is the origin of cyanobacteria considered a critical step in evolution?
- What caused the formation of banded iron formations?
- What lines of evidence indicate that microbial life was present on Earth 3.5 billion years ago?

13.3 Living Fossils: DNA Records the History of Life

The evolutionary origins of microorganisms remained a mystery until the discovery that certain molecular sequences are a record of evolutionary history (◀ Section 1.15). Mutations occur at random and accumulate over time, causing heritable changes in the sequence of DNA (Chapter 9) that drive the evolutionary process. Hence, organisms that share a recent ancestor have similar DNA sequences, and organisms that are more distantly related have DNA sequences that are more dissimilar. This means we can reconstruct the evolutionary history, or **phylogeny**, of a set of related DNA sequences by analyzing similarities in their nucleotide sequences (see Section 13.11).

The Universal Tree of Life

Carl Woese was the first to construct a **universal tree of life** that he inferred from nucleotide sequence similarity in the **ribosomal RNA (rRNA)** genes of diverse organisms (◀ Section 1.15). The universal tree of life (Figure 13.9) is a genealogy of life on Earth. It depicts the evolutionary history of all cells and clearly reveals the three-domain concept in which all cells can be classified as *Bacteria*, *Archaea*, or *Eukarya*. The root of the universal tree represents a point in time when the common ancestor of all life on Earth today, the last universal common ancestor, LUCA (Figures 13.4 and 13.9), was alive. The universal tree of life shows that the first living things were microorganisms, and that microbes were the dominant life form for most of the history of life on Earth.

Genomics (Chapter 10) supports the three-domain concept through phylogenetic analysis of most genes central to cellular function. For example, at least 60 genes (including rRNA genes) are shared by nearly all modern cells, and these genes were likely present in the universal ancestor. Most of these genes encode core functions in transcription, translation, and DNA replication. Across these conserved genes, those of *Eukarya* show greater sequence similarity to those of *Archaea* than to those of *Bacteria*. These and other data support the conclusion that the *Bacteria* and *Archaea* diverged prior to the origin of eukaryotic cells (Figure 13.9).

Horizontal Transfer and the Tree of Life

The manner in which the three domains were established remains a topic of debate. It is clear that the three domains represent the major evolutionary cell lineages that exist on Earth, and also clear that *Bacteria* and *Archaea* diverged prior to the divergence of *Eukarya* from *Archaea*. However, there are many examples of genes shared by any two of the three domains. One hypothesis is that early in the history of life, before the primary domains had diverged, *horizontal gene transfer* (Section 13.9 and Chapter 9) was extensive. During this time, any genes that provided a strong benefit likely were transferred rapidly among early forms of life (Figure 13.4). As the domains continued to diverge over time, barriers to unrestricted horizontal gene transfer evolved in order to maintain genomic stability. As a result, the previously promiscuous cell populations began to diverge into the primary lines of evolutionary descent we recognize today (Figures 13.4 and 13.9). However, the ability of genes to move horizontally between different microbial species

Figure 13.9 Schematic universal phylogenetic tree as supported by comparative analysis of small subunit (SSU) rRNA gene sequences.

Only a few key organisms or lineages are shown in each domain. The branch lengths in this tree are arbitrary, and nodes have been collapsed to reflect phylogenetic uncertainty. At least 84 phyla of *Bacteria* have now been identified, although many of these have not yet been cultured. LUCA, last universal common ancestor (Figure 13.4). The procedures used to generate phylogenetic trees are discussed in Section 13.11.

complicates our understanding of microbial phylogeny, a concept we will return to later in the chapter.

It seems likely that the domains *Bacteria* and *Archaea* had already diverged by about 3.7 billion years ago (Figure 13.1). Following this, there was a further bifurcation, somewhere between 2.7 and 1.5 billion years ago, at which time the *Eukarya* diverged from *Archaea* to form a distinct domain. As each domain continued to evolve, certain traits became fixed within each group, giving rise to a multitude of genetic, physiological, and structural differences (Chapters 2, 9, 10, and 14–18). After nearly 4 billion years of microbial evolution, we see the grand result: three domains of cellular life that are each evolutionarily distinct and yet share certain features that reveal their common descent from a universal cellular ancestor.

Before we turn our attention to the evolutionary process per se, we focus briefly on the origin of the eukaryotic cell and eventually the domain *Eukarya*, a phylogenetically distinct group (Figure 13.9) whose cell structure contrasts with the prokaryotic cell structure of

the *Bacteria* and *Archaea* (Chapter 2). The major properties and phylogenetic diversity of microbial eukaryotes are discussed in Chapter 18.

13.4 Endosymbiotic Origin of Eukaryotes

The evolution of the eukaryotic cell marked a major milestone in cellular evolution that paved the way for the evolution of complex multicellular organisms. Here we consider the origin of the *Eukarya* and show how eukaryotes are genetic chimeras containing genes from both *Archaea* and *Bacteria*.

The Last Eukaryotic Common Ancestor and Its Genetic Makeup

For around two billion years, about half the time life has existed on Earth, the Earth was anoxic and all living things had prokaryotic cell structure. The origin of the eukaryotic cell and the evolution of multicellularity roughly coincide with the oxygenation of Earth's atmosphere, and this event may have facilitated eukaryote evolution. While the exact origins of the eukaryotic cell remain unclear, the oldest microfossils that have recognizable nuclei are about 2 billion years old. Multicellular and increasingly complex microfossils of algae are evident from 1.9 to 1.4 billion years ago (Figure 13.7b). By 0.6 billion years ago, with O₂ near present-day levels, large multicellular organisms, the Ediacaran fauna, were present in the sea. In a relatively short time geologically speaking, multicellular eukaryotes diversified into the ancestors of modern-day algae, plants, fungi, and animals during what has been coined the "Cambrian explosion" (Figure 13.1).

The exact pathway by which the eukaryotic cell emerged remains a major unresolved question in evolution; however, it is clear that the modern eukaryotic cell is a genetic chimera, containing genes from both *Bacteria* and *Archaea*. By analyzing the genomes of living organisms across the tree of life (Figure 13.9), we can identify those genes that were most likely present in the *last eukaryotic common ancestor* (LECA), the ultimate ancestor of all eukaryotic organisms.

A total of about 4000 genes trace back to LECA, and this organism had all the characteristic features of eukaryotic cells. The latter included a nucleus, mitochondria that respired O₂, organelles, a complex cytoskeleton, spliceosomal machinery and genes with introns (Chapter 6), and other eukaryotic characteristics (◀ Sections 2.13–2.15). More

than 70% of these 4000 genes exist only in *Eukarya*, which clearly reveals the *Eukarya* to be a unique domain of life unambiguously differentiated from the *Bacteria* and *Archaea*. However, LECA shares its remaining genes with the *Bacteria* and *Archaea*. Of these genes, about two-thirds of them derive from *Bacteria*, whereas the remaining third are from *Archaea*. The genes of bacterial origin encode mostly metabolic functions, while the genes of archaeal origin encode the information-processing machinery of the cell. For example, eukaryotic cells share with *Archaea* molecular features of transcription and translation (Chapter 6), while features eukaryotes share with *Bacteria* include their ester-linked membrane lipids (◀ Section 2.1) and glycolytic pathway (◀ Section 3.6).

Endosymbiotic Theory

A well-supported explanation for the origin of organelles in the eukaryotic cell is the **endosymbiotic theory**, in which at least two scenarios have been proposed (Figure 13.10). This theory states that the mitochondrion of modern-day eukaryotes arose from the stable incorporation of a bacterium capable of aerobic respiration into the cytoplasm of an early eukaryotic cell. Endosymbiotic mitochondria would have been beneficial to these early eukaryotic cells because they increased the cell's respiratory capacity, and thus these early mitochondria-containing cells proceeded to become the ancestors of all living *Eukarya*. Virtually all eukaryotic cells have mitochondria (◀ Section 2.14), though these structures were subsequently lost in certain lineages of anaerobic microbial eukaryotes (Chapter 18).

A second endosymbiotic event, in an important lineage of the *Eukarya*, also had a major impact on the evolution of life. Chloroplasts arose, after the acquisition of mitochondria, from the

Figure 13.10 Endosymbiotic models for the origin of the eukaryotic cell. (a) The serial endosymbiosis hypothesis proposes that the eukaryotic ancestor diverged from the archaeal line and possessed a nucleus and other features of eukaryotic cells prior to endosymbiosis with the bacterial ancestor of the mitochondrion. A later endosymbiosis with the cyanobacterial ancestor of the

chloroplast gave rise to the eukaryotic ancestor of all plants and all other photosynthetic eukaryotes. (b) The symbiogenesis hypothesis proposes that the eukaryotic cell evolved from a symbiotic relationship between *Bacteria* and *Archaea*. The bacterial partner was eventually engulfed by its archaeal partner and evolved over time into the mitochondrion. The nucleus and other

features of the eukaryotic cell evolved after establishment of endosymbiosis. A later endosymbiosis with the cyanobacterial ancestor of the chloroplast gave rise to the eukaryotic ancestor of all plants and all other photosynthetic eukaryotes. Note the position of the mitochondrion and plastids (chloroplasts are a type of plastid) on the universal phylogenetic tree (Figure 13.9).

stable incorporation of a cyanobacterium-like cell into the cytoplasm of a eukaryotic lineage, and this endosymbiotic event triggered the origin of photosynthesis within *Eukarya* (Figure 13.10). All phototrophic eukaryotes, including plants and algae, have descended from the lineage of cells that acquired endosymbiotic chloroplasts. Atmospheric oxygen is intimately associated with the endosymbiotic origins of organelles, being consumed by the ancestor of the mitochondrion and being produced by the ancestor of the chloroplast. These endosymbiotic events diversified the metabolism of early eukaryotic cells, with mitochondria providing aerobic respiration and chloroplasts providing the ability to exploit sunlight for energy. Moreover, the endosymbiotic origin of organelles set the stage for the diversification of *Eukarya* into the forms we know today.

Several lines of evidence support the endosymbiotic theory. The earliest evidence that suggested an endosymbiotic origin of organelles was that chloroplasts and mitochondria are about the same size as bacteria and they replicate independently within the cytoplasm of the eukaryotic cell. However, the endosymbiotic theory rests largely on evidence derived from molecular biology. First, mitochondria and chloroplasts contain their own genomes composed of bacterial genes. These genomes are circular like those of *Bacteria* and encode proteins of the respiratory chain (mitochondrion) and photosynthetic apparatus (chloroplast) as well as ribosomal RNAs and transfer RNAs. Second, both mitochondria and chloroplasts contain bacterial ribosomes. The **16S rRNA** gene sequences of mitochondria and chloroplasts are also characteristic of those from *Bacteria*, and sequence analyses place the ancestor of mitochondria in the **phylum** *Proteobacteria*, and the ancestor of chloroplasts in the phylum *Cyanobacteria* (Figure 13.9). (Phyla are the major lineages of organisms within the *Bacteria*, *Archaea*, and *Eukarya*; see Section 13.12 and Table 13.1.) Third, the same antibiotics that inhibit ribosome function in free-living *Bacteria* inhibit ribosome function in these organelles. Fourth, the eukaryotic nucleus contains genes derived from *Bacteria*. Genomic sequences of eukaryotic cells have revealed genes that encode functions specific to mitochondria and chloroplasts. Moreover, because these gene sequences more closely resemble those of *Bacteria* than those of *Archaea* or *Eukarya*, it is concluded that these genes were translocated to the nucleus from ancestors of mitochondria and chloroplasts during the initial stages of endosymbiosis.

Formation of the Eukaryotic Cell

It is generally agreed that the acquisition of mitochondria was the critical event that led to the origin of the eukaryotic cell and establishment of the domain *Eukarya*. It is also thought that most of the bacterial genes found in eukaryotic genomes were transferred from the genome of the mitochondrial ancestor. However, the phylogenetic nature of the *cell* that acquired the mitochondrion remains a matter of debate; but even here, molecular evidence is paving the way to an answer.

The fact that the genes encoding DNA replication, transcription, and translation in *Eukarya* are derived from *Archaea* is generally used to support the hypothesis that the *Archaea* are ancestral to *Eukarya*. The recent discovery of *Lokiarchaeota*—a new phylum of *Archaea*—has provided fresh insights into the origin of *Eukarya*. *Lokiarchaeota* were discovered through metagenomic analyses (◀ Section 10.7) of

microbial communities that inhabit deep marine sediments near a hydrothermal vent system known as Loki's Castle (Figure 13.11), located along the Mid-Atlantic Ridge between Greenland and Norway. The genomes of *Lokiarchaeota* contain a number of eukaryotic features that suggest the presence of a eukaryotic-like cytoskeleton (◀ Section 2.15) and the ability to synthesize intracellular membranes, traits that may have facilitated stable integration of an endosymbiont. Because of these strong genetic links to eukaryotes, it is thought that *Lokiarchaeota* may be close ancestors of the cell line that ultimately gave rise to the *Eukarya*.

The exact series of events that led to the eukaryotic cell is unknown, but two major pathways have been proposed (Figure 13.10). In the *serial endosymbiosis hypothesis*, eukaryotes arose from a complex nucleus-bearing cell line that diverged from the *Archaea* and later acquired mitochondria and chloroplasts by endosymbiosis (Figure 13.10a). Endosymbiosis is posited to have occurred when this cell line engulfed or was invaded by a bacterial cell that, rather than being destroyed, managed to survive and replicate as an endosymbiont within the cytoplasm of the host cell. According to this hypothesis, eukaryotic genes that resemble those of *Bacteria* were acquired in gene transfers from the endosymbiont to the nuclear genome.

A second hypothesis for the formation of the eukaryotic cell is called *symbiogenesis* and proposes that the eukaryotic cell arose from a symbiotic relationship between cells of *Bacteria* and *Archaea* that ultimately resulted in engulfment of the bacterial partner to form mitochondria (Figure 13.10b). One version of symbiogenesis proposes that the eukaryotic cell arose from an association between a H_2 -producing species of *Bacteria* and a H_2 -consuming species of *Archaea*. This “hydrogen hypothesis” proposes that the bacterial cell was a facultative aerobe and a chemorganotroph that could grow by aerobic respiration or by syntrophic production of H_2 (▶ Section 14.22). The archaeal partner was an anaerobic chemolithotroph that required

Figure 13.11 Habitat of *Lokiarchaeota* and the origin of the *Eukarya*. *Lokiarchaeota* were discovered in a metagenomic survey of marine sediments near a hydrothermal vent system known as Loki's Castle (shown in photo). These *Archaea* share certain key similarities with *Eukarya* and might be the closest known relatives of the last eukaryotic common ancestor.

H₂ for growth. These symbiotic partners could have coevolved for an extended period prior to bacterial engulfment and formal development of the mitochondria.

The origin of the nucleus was critical to the evolution of the eukaryotic cell, yet it remains unclear whether the nucleus appeared before or after the endosymbiotic origin of mitochondria. One hypothesis for the origin of the nucleus is that its formation is associated with the evolution of RNA processing in *Eukarya*. In contrast to the genes of *Bacteria* and *Archaea*, eukaryotic genes frequently contain introns (◀ Section 6.6). For proper gene expression to occur in *Eukarya*, RNA splicing must remove introns prior to translation. Eukaryotic cells have a molecular complex called the *spliceosome* that performs RNA splicing and operates in the cell nucleus. Hence, the nuclear membrane may have evolved in *Eukarya* as a mechanism to separate spliceosomes (enzymes that can cut RNA) in the nucleus from ribosomes (major sources of RNA) in the cytoplasm.

- In what ways are modern eukaryotes a combination of attributes of *Bacteria* and *Archaea*?
- Describe the different hypotheses for the formation of the eukaryotic cell.

13.5 Viral Evolution

The tree of life does not contain viruses, and for good reason: Even though viruses show some of the properties of cells, viruses are not cells (Chapters 5 and 11). Among other cellular deficiencies, viruses lack ribosomes (and hence, ribosomal RNA), so it has been impossible to place viruses on the universal tree of life (Section 13.3 and Figure 13.9). Nevertheless, the question of when viruses first appeared on Earth and what their relationship is to cells remains an intriguing question and one to which several hypotheses have been proposed.

All known viruses require a host cell for their replication, and this leads to the natural conclusion that viruses evolved sometime *after* cells appeared on Earth. However, viruses have very few genes, they evolve rapidly, and their genes are only shared among closely related viruses. Hence there are no universally conserved viral genes. As a result, it is impossible to generate a tree of life that contains viruses, or even a universal phylogenetic tree of viruses (a phylogenetic tree of a group of viruses that share a common gene is possible, however, ▶ Figure 11.5b). Indeed, it is possible that viruses have multiple origins and that different types of viruses have evolved independently over the history of life.

Viruses as Selfish DNA

Mobile DNA elements such as plasmids and transposons are well known (see Section 13.9 and Chapter 9). These elements have been called “selfish DNA” because they replicate independently of the host chromosome, contain genes that enable their transfer between cells, have discrete host ranges, and make no contribution to an organism’s fitness (and may even be harmful). Ultimately, viruses are not much different from these selfish DNA elements. For

example, many viruses reside indefinitely in the host’s cytoplasm or integrated into its genome and do not kill the host cell immediately or at all. The main differences between viruses and mobile DNA are that viruses typically have higher rates of replication, often resulting in the death of the host cell, and viral DNA is encased in a protein capsid that facilitates transmission between cells. There exists a diversity of viral capsid proteins, however, and so it is likely that different viral families have different evolutionary origins.

One clue as to viral origins comes from the discovery of *gene transfer agents*. Gene transfer agents are bacteriophage-like particles that transfer genes between cells (▶ Section 9.7). Gene transfer agents facilitate a type of horizontal gene transfer and are encoded by genes present on the chromosome. These genes produce a capsid within which is packaged a piece of chromosomal DNA. This capsid allows for gene transfer between cells, a trait that can be beneficial for cell populations. Gene transfer agents share ancestry with viruses, but the nature of this relationship remains disputed. One possibility is that viruses appeared first and gene transfer agents evolved from defective bacteriophages. But it is also possible that gene transfer agents appeared first and viruses evolved when some of these agents gained the ability to package the genes necessary for their own production and escaped from cellular control (Figure 13.12a). It is clear that different gene transfer agents evolved independently in various lineages of bacteria and that these agents are very ancient. Hence, viruses may have evolved on multiple occasions as rogue mobile genetic elements that escaped from host control by exploiting pre-existing genetic mechanisms for DNA replication and transmission (see MicrobiologyNow on page 428).

Viruses as a Vestige of Pre-Cellular Life

Structural features shared among viral proteins have been suggested as a method to probe viral evolution. While no genes or proteins are shared among all viruses, certain structural domains, those parts of proteins that have discrete conserved functions (▶ Section 6.7), have been found in a diverse array of viruses. It is possible that the analysis of these conserved structural domains will provide new insights into how viruses first appeared on Earth.

Analyses of conserved structural domains shared among viral proteins suggests an ancient origin of viruses. Such analyses provide evidence that the earliest viruses had RNA genomes and may have existed prior to the origin of cellular life (Figure 13.12b). Some form of self-replicating RNA must have existed in the “RNA world” prior to the origin of cells (Section 13.1). Viruses may have originated from within this RNA world and taken an alternate evolutionary path from that of cellular life. Some of this pre-cellular RNA may have adapted to the appearance of cells by becoming obligate parasites. Under this scenario, viruses are a holdover from the pre-cellular days of life and have been infecting cells ever since the origin of cellular life itself.

Check Your Understanding

- Why is it difficult to place viruses on the universal tree of life?
- Explain the hypothesis that viruses have evolved many different times from mobile DNA elements.
- Explain the hypothesis that viruses first evolved prior to the appearance of cellular forms of life.

Figure 13.12 Hypothetical schemes for viral origins. (a) Gene transfer agents are mobile genetic elements that facilitate horizontal gene transfer by packaging host DNA and exporting it in a capsid. Random mutations in the DNA encoding gene transfer agents could have resulted in their escape from host control, leading to replication and transmission of infective agents that evolved into viruses. (b) Prior to the evolution of modern cells, during the RNA world (Figure 13.4), RNA-based life forms might have been highly interdependent. Following the origin of DNA, these RNA-based organisms could have evolved further dependency to the point that their replication could only take place within DNA-based cells, thereby resulting in the evolution of viruses.

II • Mechanisms of Microbial Evolution

Evolution modifies a microbe's genome over long time periods through mutations and genetic recombination. Organisms can also express new properties quickly when they receive genes from other cells. The ability of microbes to grow rapidly allows microbiologists to document evolutionary events in the laboratory.

While many of the basic principles of evolution are conserved across all domains of life, certain aspects of microbial evolution are uncommon in plants and animals. For example, *Bacteria* and *Archaea* are generally haploid and asexual, they have several mechanisms for horizontal gene transfer that result in the asymmetrical exchange of genetic material uncoupled from reproduction, and their genomes can be remarkably heterogeneous and highly dynamic. Despite these differences, we can study microbial evolution and explore the evolutionary history of life by directly comparing the genomes of living organisms. In this part of the chapter, we consider the processes that cause the diversification of microbial lineages and how these forces affect the evolution of microbial genomes.

13.6 The Evolutionary Process

In its simplest form, evolution is a change in **allele** frequencies in a population of organisms over time, resulting in descent with modification. Alleles are alternate versions of a given gene. New alleles and totally new genes arise as a result of mutation and recombination, and changes in allele frequencies can occur through a variety of processes. We see here how these simple mechanisms give rise to the origin and divergence of microbial species.

Origins of Genetic Diversity

As we have seen, **mutations** are random changes in DNA sequence that accumulate over time, and they are a fundamental source of the

natural variation that drives the evolutionary process. Most mutations are neutral or deleterious, though some can be beneficial. Mutations take several forms including *substitutions*, *deletions*, *insertions*, and *duplications* (Chapter 9). Gene duplication events produce a redundant copy of a gene that can be modified by further mutation without losing the function encoded by the original gene (Section 13.8). Hence, duplications allow for the diversification of gene function.

Recombination is a process by which segments of DNA are broken and rejoined to create new combinations of genetic material (◀ Section 9.5). Recombination can cause reassortment of genetic material already present in a genome and is also required for the integration of DNA acquired through horizontal gene transfer. Recombination can be broadly classified as either *homologous* or *non-homologous*. Homologous recombination requires short segments of highly similar DNA sequence flanking the region of DNA being transferred. By contrast, nonhomologous recombination is mediated by several mechanisms that share in common the fact that they do not require high levels of sequence similarity to initiate successful DNA integration.

Selection and Genetic Drift

New alleles and new genes result when mutation and recombination cause variation in gene sequences. Evolution occurs when different alleles change in frequency in a population over a span of many generations. Evolutionary biologists have described many different mechanisms that can govern this evolutionary process, but chief among them are the forces of *selection* and *genetic drift*.

Evolutionary selection is defined on the basis of **fitness**, the ability of an organism to produce progeny and contribute to the genetic makeup of future generations. Most mutations are *neutral* with respect to fitness and they have no effect on the cell, as a result of the degeneracy of the genetic code (◀ Section 6.9). These mutations generally accumulate in DNA over time. Some mutations are *deleterious*, and these decrease the fitness of an organism by disrupting gene function. Deleterious mutations are generally purged

from populations over time by natural selection. Some mutations can be *beneficial*, increasing the fitness of an organism, and these mutations are favored by natural selection, increasing in frequency in a population over time. An example of a beneficial mutation would be a mutation that induces antibiotic resistance in a pathogenic bacterium infecting a person undergoing antibiotic therapy. It is important to remember that all mutations occur by chance; the selective nature of the environment does not *cause* adaptive mutations but simply *selects* for the growth and reproduction of those organisms that have incurred mutations that provide a fitness advantage.

While Darwin proposed natural selection as the mechanism by which gene frequencies change over time, evolutionary change can occur through mechanisms other than selection. A chief example is **genetic drift** (Figure 13.13), a random process that can cause gene frequencies to change over time, resulting in evolution in the absence of natural selection. Genetic drift occurs because some members of a population will have more offspring than others simply as a result of chance. Over time, these chance events can result

in evolutionary change in the absence of selection. Genetic drift is most powerful in small populations and in populations that experience frequent “bottleneck” events. The latter occur when a population experiences a severe reduction in population size followed by regrowth from the cells that remain. For example, genetic drift can be very important in the evolution of pathogens because each new infection is caused by a small number of cells colonizing a new host. Hence, pathogen populations can change rapidly as a result of random genetic drift (Figure 13.13).

Origins of Microbial Species

Microbial species can be very old and can encompass a wide variety of individual strains having diverse traits (we consider the microbial species concept in Section 13.12). The accumulation of mutations over time can be used to explore the evolutionary origins of species. Sequence changes due to mutation can be used as a **molecular clock** to estimate the time since a species has diverged from its closest relatives. Major assumptions of the molecular clock approach are

Figure 13.13 Genetic drift. Genetic drift is a random process that can cause gene frequencies in a population to change over time, causing evolution without natural selection. In this example, a population containing four different bacterial genotypes (indicated by different colors), each at equal frequency, is present in the ancestor tube. Four cells at random are then transferred to each of three new tubes and the cells allowed to grow to fill each tube. There is no difference in fitness between the cells and so they grow equally. Cells taken at random are then transferred in two successive rounds. Striking differences in genotype frequencies between the populations are observed after only three rounds of transfers.

that nucleotide changes accumulate in a sequence in proportion to time, that such changes are generally neutral and do not interfere with gene function, and that they are random. Molecular clock estimates are most reliable when they can be calibrated with evidence from the geological record. The most well documented of these have used obligate bacterial symbionts of insects (► Section 23.7) for which the insect host provides a fossil record to accurately date evolutionary events.

Molecular clock estimates make it possible to estimate the divergence of microbial species based on dissimilarity in their gene sequences. For example, molecular clock estimates indicate that the closely related species *Escherichia coli* and *Salmonella enterica* (*typhimurium*), which have 2.8% dissimilarity in their 16S rRNA gene sequences, last shared a common ancestor some 100–140 million years ago. Likewise, it is estimated that two well-characterized strains of *E. coli*, the harmless strain K-12 and the foodborne pathogenic strain O157:H7 (► Section 33.11), diverged about 4.5 million years ago. Many microbial species, like *E. coli*, can encompass an enormous number of different strains possessing a diversity of traits that collectively define the species. Molecular clock estimates reveal that microbial speciation takes a very long time. However, we will see in the next section that while speciation can take a long time, strains of a species can acquire new traits rapidly.

Check Your Understanding

- How do gene duplication and recombination result in genetic diversity?
- How are molecular clock estimates used to infer evolutionary origins of species?

13.7 Experimental Evolution

Experimental evolution is a field that employs laboratory experiments with microorganisms to investigate evolutionary processes. Such evolution experiments are enabled by the rapid growth of bacteria and the ability to preserve them indefinitely by freezing. The latter makes it possible to maintain a living “fossil record” of ancestral organisms that can be thawed later and grown to compare with evolved strains. Microorganisms typically form large populations and can reproduce quickly, producing a new generation in as few as 20 minutes for some species, and thus evolutionary events in microbial populations can often be observed in the laboratory on relatively short time scales. Here we consider two examples of rapid evolutionary change in bacteria, one involving the rapid *loss* of a characteristic trait in *Rhodobacter*, and one involving the *acquisition* of a new trait in *Escherichia coli*.

Loss of Function

Rhodobacter is a phototrophic purple bacterium that carries out anoxygenic photosynthesis (► Section 14.5) in illuminated anoxic environments in nature. When cultured anaerobically, the cells synthesize photopigments in both the presence and the absence of light because pigment synthesis is regulated by O₂ availability and not by light. In the light these pigments participate in photosynthetic reactions that lead to ATP synthesis, but in darkness, the pigments provide no benefit to the cell. Random mutations, by chance,

occasionally generate *Rhodobacter* cells that produce reduced levels of photopigments. In nature, the ability to carry out photosynthesis provides a fitness benefit and wild-type cells outcompete such pigment-deficient mutants. However, when cultured in constant darkness, wild-type cells have no such advantage. In darkness, mutants that produce reduced levels of photopigments gain the advantage because they do not waste energy and resources synthesizing photopigments that provide them no benefit. As a result, photopigment mutants can grow at a faster rate and quickly take over *Rhodobacter* cultures grown in darkness because under these conditions, the mutants have greater fitness than wild-type cells (Figure 13.14). Mutations affecting photosynthesis occur at the same rate in the light as in the dark, but in the light the selection for the wild-type phototrophic phenotype is so strong that photopigment mutants are quickly lost from the population.

Gain of Function

The *E. coli* long-term evolution experiment (LTEE), which has been running since 1988, has tracked the evolution of 12 parallel lines of *E. coli* through more than 60,000 generations. The *E. coli* LTEE cultures have been grown aerobically on a minimal medium with glucose as a sole source of carbon and energy. *E. coli* is typically

Figure 13.14 Survival of the fittest and natural selection in a population of phototrophic purple bacteria. Serial subculture of the purple bacterium *Rhodobacter capsulatus* in the light (green line) provides a benefit to wild-type phototrophic strains and they outcompete nonphototrophic mutants. In the dark (blue line), however, phototrophy provides no benefits and nonphototrophic mutants quickly outcompete wild-type cells still making bacteriochlorophyll and carotenoids. Photos: top, plate culture showing colonies of phototrophic cells of *R. capsulatus*; bottom, close-up photos showing the color of colonies of wild-type cells and five pigment mutants (1–5) obtained during serial dark subculture. Wild-type cells are reddish-brown from their assortment of carotenoid pigments. The color of mutant colonies reflects the absence (or reduced synthesis) of one or more carotenoids. Mutant strain 5 lacked bacteriochlorophyll and was no longer able to grow phototrophically. Mutant strains 1–4 could grow phototrophically but at reduced growth rates from the wild type. Data adapted from Madigan, M.T., et al. 1982. *J. Bacteriol.* 150: 1422.

propagated in a rich medium that contains an excess of nutrients, and so the minimal glucose medium used in the LTEE represents a new adaptive environment in which *E. coli* can evolve over time.

In the LTEE, both the ancestor and the evolved lines were genetically engineered to contain a neutral marker that made their colonies either red or white. The marker made it possible to measure the fitness of evolved strains relative to the ancestor by putting them into competition with one another (Figure 13.15a). Genome sequencing during the experiment revealed that mutations accumulated randomly over time in the evolved lines. However, the relative fitness of the evolved lines on minimal glucose medium increased dramatically over the first 500 generations as a result of selection acting on mutations beneficial in this new environment (Figure 13.15b). The fitness of the evolved lines continued to increase, albeit at a reduced rate, as a result of further selection over the course of the experiment. Most remarkably, after 31,500 generations, one of the evolved lines obtained the ability to use citrate as an energy source (Figure 13.15c). Citrate was present as a pH buffer in the growth medium and was not considered a potential carbon source for *E. coli*, because the inability to grow aerobically on citrate is a diagnostic trait used for identifying *E. coli*. However, the random accumulation of mutations in this one evolved line modified preexisting genes in such a way as to allow for the evolution of a new adaptive trait. The diverged strains can now exploit a new resource that was unavailable to the ancestral population. Since they can now catabolize both citrate and glucose, these cells grow to higher cell density than the ancestor (Figure 13.15c). The fact that only one of the 12 parallel lines evolved the ability to grow on citrate demonstrates the chance nature of evolution.

The transitions shown in these experiments remind us of how quickly evolutionary pressures can shift even major properties (such as metabolic strategies) of a microbial cell population. In the case of *Rhodobacter* (Figure 13.14) a mutation that is deleterious in the wild provides a selective advantage when the organism is grown in the laboratory in a continuously dark environment. Under this new condition, evolution causes *Rhodobacter* to lose unneeded metabolic machinery. In the case of *E. coli* (Figure 13.15), the accumulation of random mutations set the stage for genetic diversity in a population. That is, natural variation caused by spontaneous mutation generated a new trait—the ability to use citrate—and since the environment in which the cells were grown happened to contain citrate, this mutation provided a selective advantage to those cells. In the absence of citrate, these mutations would still occur at the same rate. However, in the absence of a selective benefit, cells able to use citrate would likely disappear from the population over time.

Check Your Understanding

- In the experiment of Figure 13.14, why did the cell population in the dark lose its pigments?
- Why did only one of twelve *Escherichia coli* populations in the LTEE eventually evolve the ability to grow on citrate? What does this tell us about the process of evolution?
- In the LTEE, if the rate of mutation in *E. coli* remains constant, then why does the fitness of *E. coli* improve rapidly upon initial addition to a new environment and then more slowly in later generations (as in Figure 13.15)?

Figure 13.15 Long-term evolution of *Escherichia coli*. (a) In the *E. coli* long-term evolution experiment (LTEE), ancestral and derived lines differ in a mutation that affects their ability to use arabinose, allowing them to be differentiated by their colony color when grown on tetrazolium arabinose agar. (b) Competition experiments between evolved and ancestral strains show that relative fitness in minimal glucose media increases dramatically for evolved lines. (c) The ability to use citrate aerobically evolved in one of 12 LTEE lines. Cells growing on minimal and citrate allowed the mutant cell line to reach significantly higher cell densities. Relative fitness is a measure of the growth rate of the evolved strain to that of the ancestral strain. Note that the mutation rate in the *E. coli* cultures is constant and that mutations accumulate randomly over time.

13.8 Gene Families, Duplications, and Deletions

The duplication and deletion of genetic information within the genome plays a major role in microbial evolution. Genomes vary dramatically in size (Chapter 10), and duplication and deletion mutations are a major force that governs the size of microbial genomes. In addition, these mutations govern the gene content of the genome, allowing for removal of nonessential genes and the expansion of gene function. In order to examine the impact of deletions and duplications on the evolution of microbial genomes, we must first classify genes based on their shared ancestry so that we can compare the presence and absence of genes across genomes.

Duplications and Gene Families

A set of genes that have all descended from a single ancestral gene present in a shared ancestor are **homologs** (Figure 13.16). Homologous genes tend to have similar nucleotide sequences, and we can infer homology based on nucleotide similarity. Genes that are highly similar in sequence often have the same function, and homologous genes that share the same function are **orthologs**.

Figure 13.16 Homologs. This family tree depicts the evolution of a gene family composed of homologous genes (orthologs and paralogs), which means that all have evolved from a single ancestral gene present in an ancestral species. A gene duplication occurs in the ancestral species, allowing the redundant gene copy, gene B, to evolve a new function within the genome of the ancestral species (see Figure 13.17a). Over time, the ancestral species evolves into two new species whose gene sequences have diverged as a result of evolution. Genes A1 and A2 have the same functions and they have evolved from the same ancestral gene, and so they are orthologs, as are B1 and B2. Genes that have evolved from the same ancestral gene but have different functions are paralogs.

However, not all homologous genes have the same function. The accumulation of mutations over time can eventually cause genes to evolve new functions. Genes that are homologous but have different functions are **paralogs**. Over time a single ancestral gene sequence can diverge to have many different functions in many different organisms. A group of homologous genes is called a **gene family**, and gene families can contain diverse paralogs that all share a common evolutionary origin.

Gene duplication is thought to be a major driving force behind the evolution of gene families and the organisms that contain them (Figure 13.17a). A duplication mutation creates a redundant copy of a gene sequence in the genome. The original gene copy retains its function, making it possible for the second copy to accumulate mutations freely without a loss of gene function in the cell. In this way, evolution can “experiment” with one copy of the gene. Genomic analyses have revealed many examples of protein-encoding genes that were clearly derived from gene duplication. Figure 13.17b shows this for the enzyme RuBisCO, a key enzyme of autotrophic metabolism (◀ Section 3.12): An ancestral RuBisCO gene gave rise to paralogous enzymes with different but related catalytic activities.

Gene Deletions in Microbial Genomes

Gene deletions play an important role in microbial genome dynamics. It is a common misconception that evolution inevitably causes organisms to increase in complexity over time. In reality, evolution is both a give and a take proposition. Fitness changes are completely dependent on the environment, and fitness in some environments can actually be improved by deletion of genetic material.

It is common in prokaryotic cells for nonessential and nonfunctional materials to be deleted over evolutionary time. Deletions occur with far greater frequency than insertions or duplications in microbial genomes. This bias toward deletions is the force that maintains the small size of many microbial genomes and the reason why the genomes of *Bacteria* and *Archaea* are tightly packed with genes and contain relatively few noncoding sequences (◀ Section 10.3). Selection is the main force that counters the effect of deletions, preserving those genes that provide a fitness benefit to the cell.

Deletions are also thought to be a driving force for the tiny genomes observed in many obligate intracellular symbionts and intracellular pathogens (◀ Section 10.3 and ▶ Section 23.7). The genomes of these bacteria are highly streamlined because many metabolites are available in the cytoplasm of their host organisms. Hence deletion mutations that remove biosynthetic genes might have little effect on the fitness of an intracellular pathogen if those biosynthetic functions are provided by the host. Over time, deletion mutations eliminate redundant functions. Insect endosymbionts have carried this theme to an extreme and show the smallest of all cellular genomes (◀ Section 10.3, Table 10.1, and Figure 10.8). The same process is ultimately responsible for the minute genomes found in mitochondria and chloroplasts (◀ Section 10.4).

Deletion Mutations and the Evolution of Interdependence in Microbial Communities

A deletion mutation that prevents an organism from producing an essential nutrient such as a vitamin when growing in pure culture would be a lethal event. But in nature, microorganisms grow in

Figure 13.17 Evolution by gene duplication. (a) The principle of gene duplication. After duplication, the “spare” copy of a gene is free to evolve to encode a new function. (b) The large subunit of the enzyme RuBisCO, which fixes CO_2 during photosynthesis, is part of a gene family that contains many different genes. Different orthologous forms of RuBisCO (forms I, II, and III), which all retain the same function, are present in different microbial groups. However, RuBisCO is in turn derived from an ancestral gene (black bars) of unknown function that was duplicated to produce paralogous genes encoding an enzyme in methionine metabolism (yellow bar) and several genes whose function is still unknown (purple bars). RLP, RuBisCO-like protein.

microbial communities, and in such a setting, a deletion mutation that prevents an organism from producing an essential nutrient may not be lethal if the organism can obtain the nutrient from some other organism in the environment (**Figure 13.18**).

All genes impose some cost on the cell, and organisms living in a microbial community can delete a gene to avoid this cost if other community members provide the gene’s function. Such deletions can increase an organism’s fitness but promote the interdependency of

members of the microbial community. Organisms having such “loss-of-function” mutations will remain competitive as long as they remain within the community but may be unable to grow if separated from the community in which they coevolved. This sharing of resources in natural communities explains the observation that many bacteria grown in pure culture require one or more growth factors. For example, regardless of where they are isolated from, all strains of the phototrophic purple bacterium *Rhodospirillum rubrum* require the vitamin

Figure 13.18 The evolution of interdependence in microbial communities. (a) Three species in a community each have three different genes that make extracellular products that benefit the whole community (a gene and its product are shown in the same color). (b) Over time, random mutations cause functions to be lost from the genomes. (c) As long as some members of the community continue to make each product, there will be no fitness cost when a single species loses a single gene. Over time, the three species become mutually dependent.

biotin when grown in pure culture, while all strains of *Rhodobacter capsulatus* (see Figure 13.14) require thiamine. In nature, these two phototrophs could coexist in the same microbial community if each phototroph (or other microbes in the community) secreted a small amount of the vitamin that the other phototroph required. Such gene deletions result in metabolic interdependencies within a microbial community (Figure 13.18), making deletions one of the factors that govern the microbial composition of a microbial community.

Many microbes can grow in pure culture without any growth factor additions. Such organisms preserve all essential functions and bear the costs of maintaining all gene functions; this puts them at a disadvantage relative to mutually dependent competitors when the competition takes place within a complex microbial community. However, cells that maintain their ability to grow independently earn a fitness bonus in that, unlike their mutually dependent competitors, they retain the option of dispersing to new habitats and growing there independently.

13.9 Horizontal Gene Transfer

Microorganisms can exchange DNA between cells through the process of **horizontal gene transfer** (Figure 13.19), and this process has a tremendous impact on microbial evolution. We often think of evolution as a vertical process that takes place along the branches of a phylogenetic tree starting with an ancestor at the tree's root and ending with descendants at its topmost branches. However, horizontal gene transfer allows the transfer of DNA between distant branches of the tree. At least three mechanisms of horizontal gene transfer exist: *transformation*, *transduction*, and *conjugation* (Figure 13.19 and Chapter 9).

Horizontal gene transfer can be thought of as a type of recombination in which DNA from the donor is passed to the recipient and becomes part of the recipient's genome. Horizontal transfer is unlike sexual recombination because it is (1) unidirectional, with DNA passing from donor to recipient, (2) asymmetrical, in that only a small amount of DNA is usually transferred, and (3) not constrained by species boundaries because the donor and recipient can be distantly related.

Horizontal gene transfer can have a range of consequences depending on the mechanism of recombination used to incorporate the DNA into the genome. The effect of horizontal transfer on the genome is strictly additive when the newly acquired DNA is inserted by nonhomologous recombination. However, when the newly acquired DNA is incorporated by homologous recombination, the result can be *gene conversion*, in which the recipient's copy of a gene is replaced by the donor's copy.

Like most mutations, most genes acquired by horizontal gene transfer can be expected to be neutral or deleterious to the cell. Hence, horizontally acquired genes that do not convey a fitness benefit are deleted from the genome over time. In contrast, those genes that do confer a fitness benefit are likely to persist within the

Figure 13.19 Vertical versus horizontal gene transfer. Vertical gene transfer occurs when cells divide. Horizontal gene transfer occurs when a donor cell contributes DNA to a recipient cell. In *Bacteria* and *Archaea*, horizontal transfer occurs through one of three mechanisms: transformation, transduction, and conjugation.

genome. Horizontal gene transfer allows a cell to “explore” a tremendous diversity of genetic information, and newly acquired genes can change over time as a result of further mutation and recombination. As a result, horizontal gene transfer is an effective means for microbes to acquire new functions and to evolve new traits.

The Mobilome

Horizontal gene transfer is facilitated by the **mobilome**, the sum total of all mobile genetic elements in a genome. Mobile genetic elements are discrete segments of DNA that have genes encoding their own replication, recombination, and transmission. Mobile genetic elements include plasmids, prophages (integrated viral genomes), insertion sequences, transposons, and integrons (Chapter 9). Although the mobilome is not essential to the cell, it can nevertheless play an important role in genome evolution by shuffling genes within and between genomes.

Insertion sequences are simple mobile elements that consist of a *transposase* gene flanked by inverted repeats (◀ Section 9.11). Transposase is an enzyme that recognizes the inverted repeats and catalyzes nonhomologous recombination, allowing the insertion sequence to jump between different segments of DNA through a “cut and paste” mechanism. If multiple insertion sequences are present in a genome, these elements can generate chromosomal rearrangements such as deletions, inversions, or translocations (Figure 13.20). In addition, insertion sequences shared between a chromosome and a plasmid can facilitate the exchange of genes between these molecules.

Transposons are mobile genetic elements that are larger than insertion sequences but similar in function, having both terminal inverted repeats and a transposase gene (◀ Section 9.11). Transposons, however, contain multiple genes that can have a diversity of functions unrelated to transposition. Hence, transposons can move a wide variety of genes between different segments of DNA. Furthermore, some transposons contain genes that cause conjugative transfer, thereby promoting horizontal transfer between cells by conjugation. Because of this tendency, transposable elements are a strong driver of genome evolution.

Integrans also facilitate recombination and DNA exchange. Integrans contain an *integrase* gene flanked by a promoter and a

Figure 13.20 Mobile elements promote genome evolution. Mobile genetic elements facilitate the transfer of DNA from one organism to another, thus adding new genes to the recipient genome. The most common mobile genetic elements are plasmids, bacteriophages, and transposons. Mobile genetic elements can also facilitate chromosomal rearrangements. For example, transposase can cause deletions and inversions of host DNA next to sites of transposon insertion.

recombination site that contains direct repeats. Integrins typically contain a gene cassette consisting of one or more genes flanked by a series of corresponding recombination sites. The integrin promoter drives the expression of genes within the cassette. The integrase catalyzes site-specific recombination of DNA at the integrin recombination site. Hence, DNA sequences flanked by corresponding recombination sites can be inserted or excised from the integrin gene cassette. Integrins are often found on other mobile elements such as plasmids or transposons. This mechanism can facilitate the rapid acquisition and rearrangement of new genes.

Detecting Horizontal Gene Flow

The rate of horizontal gene transfer per cell per generation is quite low, but the effect of horizontal gene transfer on genome composition is integrated over the entire evolutionary history of an organism dating back to the last universal common ancestor. As a consequence, the vast majority of genes in a microbial genome have been subject to horizontal gene transfer at some point in their evolutionary history. However, detecting horizontally transferred genes and unraveling their evolutionary history can be a challenge.

A variety of methods are used to identify horizontally transferred genes, but these methods typically take one of two different approaches: statistical analysis of sequence composition, or phylogenetic analysis. Microbial genomes often have distinguishing nucleotide sequence characteristics, much like a fingerprint, that can be used in their identification. These differences in sequence

composition can be used to identify segments of DNA acquired from other organisms. One example is to compute the percentage of G + C (guanine–cytosine) base pairs in the genome (genomic GC content, ◀ Figure 10.8). In this case, horizontal gene transfer is signaled if the percentage of G + C base pairs in a segment of DNA differs significantly from that of the rest of the genome. In addition, genomes also contain DNA corresponding to each of the 64 possible codons at different frequencies, and these codon-use frequencies (codon bias, ◀ Section 10.2) can also be used to identify horizontally acquired genes. A variety of statistical tests can be applied to look for such differences in sequence composition across the genome.

Horizontally acquired genes can also be detected through phylogenetic analysis by making phylogenetic trees for different genes in the genome (Section 13.11). If a gene has a different pattern of ancestry from the rest of the genes in the genome, that is an indication that it was horizontally transferred. Horizontally transferred genes are most easily detected when they are transferred between highly dissimilar organisms and more difficult to detect when transferred between close relatives.

We move on now from the effects of horizontal transfers of individual genes or sets of genes to consider the evolution of the entire genome.

13.10 The Evolution of Microbial Genomes

Comparative genomics makes use of whole genome sequencing technologies (Chapter 10) to analyze differences in gene content and DNA sequence composition across entire sets of genomes. Comparative analyses have revealed microbial genomes to be highly diverse and dynamic. A microbial species is composed of many individual strains that differ in gene composition. In the case of microbial genomes, those differences in gene composition can be substantial. Figure 13.21 illustrates the diverse nature of microbial genomes within a single species of the genus *Salmonella*. All strains of *S. enterica*—an important human pathogen (▶ Section 33.10)—whose genomes have been sequenced share 2811 genes, but each strain of this species also has a unique set of *strain-specific* genes. The genomes of many microbial species, like *S. enterica*, are evolving constantly as diverse strains gain genes by horizontal gene transfer and lose genes as a result of deletions.

From genomic studies of several strains of a single species, it is now clear that the genome of a microbial species is really composed of two segments: the **core genome**, consisting of genes shared by all individual strains of a species, and the **pan genome**, consisting of the core genome *plus* genes that are not shared by all strains of a species (Figure 13.22a). As we have seen, horizontal gene transfer of mobile genetic elements (Section 13.9) is widespread. The existence of the pan genome shows that microbes are constantly sampling genes from

Figure 13.21 The *Salmonella enterica* pan genome includes a large number of strain-specific genes. The species *Salmonella enterica* contains many different strains that differ in various traits including their pathogenicity. While these strains all share the same 2811 core genes, each individual has some number of strain-specific genes. *Salmonella bongori* is a species distinct from *S. enterica*. Data from Jacobsen, A., R.S. Hendriksen, F.M. Aarestrup, D.W. Ussery, and C. Friis. 2011. The *Salmonella enterica* pan-genome. *Microb. Ecol.* 62: 487.

other organisms in the environments in which they live. Consequently, there can be major differences in genome size, gene content, and functional traits (virulence, symbiosis, biodegradation, and the like) between individual strains within a single microbial species.

The Dynamic Nature of the *Escherichia coli* Genome

The dynamic nature of microbial genomes was revealed in dramatic fashion when the first genomes were sequenced from multiple strains of a single species. For example, genome sequencing of *Escherichia coli* strain K-12 and two pathogenic strains showed that only 39% of their genes were shared among all three genomes (Figure 13.22). The three genomes varied in size by more than a million base pairs and each contained a unique and diverse complement of genes acquired through horizontal gene transfer.

E. coli genomes have on average 4721 genes, with individual strains having as few as 4068 or as many as 5379 total genes. The core genome consists of only 1976 genes present in all strains, accounting for less than half the genes present in the average *E. coli* genome. The size of the core genome can be expected to decrease as the evolutionary distance of strains increases.

The number of unique genes observed in *E. coli*, and the size of its pan genome, continues to increase indefinitely as each new strain of *E. coli* has its genome sequenced. For example, a survey of genomes from 20 *E. coli* strains revealed a total of 17,838 unique genes (Figure 13.22b). Subtracting the contribution from the core genome, this indicates that as many as 15,862 genes are not shared by all strains. A great many of these genes have clearly been obtained from horizontal gene transfers rather than through vertical patterns of inheritance. Patterns of gene exchange appear to be governed by

Figure 13.22 The core and pan genome concept. Microbial genomes are dynamic and heterogeneous. The first three genomes sequenced from different strains of *Escherichia coli* were found to have only 39% of their genes in common. The core genome is considered the set of genes that are shared by all members of a species (darkest green in part a), while the pan genome is the totality of all genes found in the different strains of a species (all the genes in genomes 1–3 in part a). The size of the core and pan genome can vary between species. In *E. coli* the core genome is composed of approximately 1976 genes (b). The size of the pan genome in *E. coli* is not fixed, as each different strain has a unique complement of genes acquired from horizontal gene transfers. Data adapted from Touchon, M., et al. 2009. *PLoS Genetics* 5(1): e1000344.

phylogenetic distance, with rates of gene exchange declining as the phylogenetic distance increases between genomes. In the core genome of *E. coli*, for example, it has been found that most horizontal gene transfer takes place between close relatives and occurs by homologous recombination of DNA segments of 50 to 500 base pairs in length.

Chromosomal Islands

Comparative genomic analyses have revealed that in addition to a gene or two, *entire genetic pathways* can be acquired as a result of horizontal gene transfer. These so-called **chromosomal islands** (also called *genomic islands*) contain clusters of genes for specialized functions (Figure 13.23). Several lines of evidence indicate that chromosomal islands derive from horizontal gene transfer. First, chromosomal islands are often flanked by inverted repeats, implying that the whole region was inserted into the chromosome by transposition (Section 13.9). Second, the base composition and codon bias in chromosomal islands often differ significantly from those of the genome proper. Third, chromosomal islands often belong to the pan genome, being found in some but not all strains of a species. In addition, some chromosomal islands carry an integrase gene, suggesting similarity

Figure 13.23 Chromosomal islands and pathogenicity islands in *Escherichia coli*. Genome comparisons of nonpathogenic *E. coli* strain K-12 and pathogenic *E. coli* strains 536 and 073 (both of which cause urinary tract infections) reveal that many differences in gene content are associated with chromosomal islands (CI) and pathogenicity islands (PAI). The inner ring represents genome position (in base pairs). The middle ring shows the frequency with which G + C base pairs occur across the genome, and anomalous regions are colored red. The outer ring compares gene content between genomes: green, genes common to all strains; red, genes present only in pathogenic strains; blue, genes found only in strain 536; orange, genes of strain 536 present in a different location in strain 073. Note the correlation between chromosomal islands and skewed GC content. Some very small inserts are deleted for clarity. Prophage, DNA from a temperate bacteriophage. Data adapted from Brzuszkiewicz, E., et al. 2006. *Proc. Natl. Acad. Sci. (USA)* 103: 12879.

with mobile elements such as conjugative transposons (Section 13.9). Finally, in a few cases, the transfer of chromosomal islands has even been demonstrated experimentally in the laboratory.

Chromosomal islands that encode *virulence factors*, molecules that facilitate disease and are found in pathogenic bacteria (Chapter 25), are called **pathogenicity islands**. The pathogenicity islands of uropathogenic strains of *E. coli* have been particularly well studied (Figure 13.23). Only a few strains of *E. coli* cause bladder and kidney infections, but those that do—the uropathogenic strains—contain pathogenicity islands that encode a variety of virulence factors including adhesins that facilitate binding to host tissues and a capsule that helps cells evade immune surveillance. Pathogenicity islands are also present in certain pathogenic strains of the gram-positive bacterium *Staphylococcus aureus*, which can cause serious skin infections (► Section 31.9). These pathogenicity islands can be moved between cells by transduction, a major mechanism of horizontal gene transfer (◄ Section 9.7).

Chromosomal islands in pathogenic bacteria have drawn the most attention from microbiologists because in many cases, genes encoding disease-associated functions have been linked to an island.

However, chromosomal islands are also known whose genes encode proteins that degrade pollutants such as aromatic hydrocarbons and herbicides (► Section 22.4). In addition, many of the genes essential for the symbiotic relationship of species of the nitrogen-fixing bacterium *Rhizobium* with the root nodules of plants (► Section 23.4) are carried in chromosomal islands. Perhaps the most unique chromosomal island is the magnetosome island of the bacterium *Magnetospirillum*; this DNA fragment carries genes that encode the formation of magnetosomes, intracellular magnetic particles that orient the cell in a magnetic field and influence the direction of its movement (◄ Section 2.12).

In the final part of this chapter we consider how phylogenetics has revolutionized microbial systematics and has begun to crystallize our concept of a microbial species.

III • Microbial Phylogeny and Systematics

Microbial systematics blends phenotypic and genotypic information about microbes to yield a working blueprint of how the microbial world evolved and how it is organized. Phylogenetic trees are an important part of this blueprint and are used to show the evolutionary connections between microbes and to describe new taxa.

Systematics is the study of the diversity of organisms and their relationships. It links **phylogeny** with **taxonomy**, the science in which organisms are characterized, named, and classified according to defined criteria. Taxonomists describe microorganisms using a *polyphasic approach* that evaluates *phenotypic*, *genotypic*, and *phylogenetic* information. Phenotypic analyses examine the morphological, metabolic, physiological, and chemical characteristics of the cell. Genotypic analyses consider characteristics of the genome. These two analyses are used to categorize organisms based on similarities and are complemented by phylogenetic analyses, which seek to place organisms within an evolutionary framework using molecular sequence data (see Figure 13.9). We begin by exploring how molecular sequences can provide phylogenetic insight.

13.11 Molecular Phylogeny: Making Sense of Molecular Sequences

Molecular sequences provide a record of past evolutionary events and can be used to build **phylogenetic trees**, which are diagrams that depict evolutionary history. As we have seen in this chapter, mutations accumulate in DNA sequences over time. These mutations occur at random and are a major source of the natural variation that makes evolution possible (Section 13.6). Hence, the number of

nucleotide sequence differences between any two homologous genes will be a function of the number of mutations that have accumulated since they shared a common ancestor. As a result, differences in DNA sequences can be used to infer evolutionary relationships, and the technology for doing this is well developed.

Obtaining DNA Sequences

Obtaining DNA from a microorganism is relatively easy if the organism can be cultivated in isolation in the laboratory. Once the

cultivar's genomic DNA is isolated, either the genome can be sequenced directly or the genomic DNA can be used to amplify one or more specific genes, using the polymerase chain reaction (PCR, ◀ Section 12.1) and primers specific for the gene(s) of interest. Advances in DNA sequencing technology (◀ Section 10.2) have made genome sequencing a standard tool employed in analyses of microbial phylogeny. However, sequence analysis of small subunit (SSU) ribosomal RNA (rRNA) genes (Figure 13.24), which encode the rRNA molecule found within the small subunit of the ribosome

Figure 13.24 Ribosomal RNA (rRNA). Primary and secondary structure of 16S rRNA from *Escherichia coli* (Bacteria). The 16S rRNA from *Archaea* is similar in secondary structure (folding) to that of *Bacteria* but has numerous differences in primary structure (sequence). The molecule is composed of conserved and variable regions (V1–V9). The approximate positions of the variable regions are indicated in color. Inset: the 70S ribosome of *Bacteria* is composed of 30S and 50S subunits; 16S rRNA is part of the 30S subunit whereas 5S and 23S rRNAs are parts of the 50S subunit.

Figure 13.25 PCR amplification of the 16S rRNA gene from an unknown microbial culture. Following DNA isolation, primers complementary to the ends of the 16S rRNA (Figure 13.24) are used to PCR-amplify the 16S rRNA gene from the genomic DNA of the bacterium. The PCR product is then run on an agarose gel (lane 1) versus a standard (lane 2). The bands of amplified DNA are approximately 1465 nucleotides in length (positions that DNA of different lengths would run in the gel are indicated at the left). The band from the unknown culture is then excised from the gel, purified, and sequenced. The sequence is then aligned with 16S rRNA sequences from other organisms and a phylogenetic tree constructed.

(◀ Section 6.10), remains a cornerstone of molecular phylogeny in microbiology because **SSU rRNA** genes are highly conserved, present in all cellular organisms, and easily sequenced and analyzed (see Figure 13.9).

PCR primers exist for many highly conserved genes, such as the SSU rRNA gene, and can be designed in such a way as to have different levels of phylogenetic specificity. That is, primers can be designed that target distinct species (or all species) within a genus, all genera within a phylum, or all phyla within a domain, and there are even “universal” PCR primers that will amplify the SSU rRNA gene from any organism. PCR products are visualized by agarose gel electrophoresis, excised from the gel, extracted and purified from the agarose, and then sequenced, often using the same oligonucleotides as primers for the sequencing reactions (Figure 13.25). Instead of starting with a microbial culture, it is also possible to amplify SSU rRNA genes from DNA extracted directly from an environmental sample or to sequence environmental DNA directly without amplification (metagenomics, ▶ Section 10.7 and ▶ Section 19.6). These latter approaches are widely used to characterize microorganisms that are difficult or not yet possible to grow in laboratory culture. Once sequences are obtained, they must be aligned and analyzed, issues we turn to now.

Sequence Alignment

Phylogeny can be inferred only from genes that have homology, that is, *genes that have been inherited from a common ancestor*. Thus, homology is a binary trait; sequences are either homologous or they are not. The concept of homology is often confused with that of sequence similarity. The latter is a continuous trait defined as a percentage of nucleotide positions shared between any two sequences. Sequence similarity is used to infer homology, but a similarity value can be calculated between any two sequences regardless of their function or evolutionary relationship. Thus, the terms similarity and homology are not interchangeable. Genes that have homology can be either orthologs, if they have the same function and originate from a single ancestral gene in a common ancestor, or paralogs, if

they have evolved to have different functions as a result of gene duplication (Section 13.8 and Figures 13.16 and 13.17). Phylogenetic analyses typically focus on analyses of orthologous genes because of their common phylogeny and function.

Phylogenetic analyses estimate evolutionary changes from the number of sequence differences across a set of homologous nucleotide positions. Some mutations introduce nucleotide insertions or deletions, and these cause gene sequences to differ in length, making it necessary to **align** nucleotide positions prior to phylogenetic analysis of gene sequences. The purpose of **sequence alignment** is to add gaps to molecular sequences in order to establish positional homology; that is, to be sure that each position in the sequence was inherited from a common ancestor of all organisms under consideration (Figure 13.26). Proper sequence alignment is critical to phylogenetic

analysis because the assignment of mismatches and gaps caused by deletions is in effect an explicit hypothesis of how the sequences have diverged from a common ancestral sequence.

Phylogenetic Trees: Composition and Construction

A phylogenetic tree is a diagram that depicts the evolutionary history of the organisms on the tree and bears some resemblance to a family tree. Most microbes have not left fossils and so their ancestors are unknown, but ancestral relationships can be inferred from the DNA sequences of organisms that are alive today. Organisms that share a recent ancestor are likely to share other characteristics as well, and thus phylogenetic trees allow us to make predictions about an organism's characteristics. Phylogenetic trees are also of great use in taxonomy and species identification, as we will discuss later (Section 13.12).

A phylogenetic tree is composed of *nodes* and *branches* (Figure 13.27). The tips of the branches in a phylogenetic tree represent species that exist today. The nodes represent a past stage of evolution where an ancestor diverged into two new lineages. The branch length represents the number of changes that have occurred along that branch. In a phylogenetic tree, only the position of nodes and the branch lengths are informative; rotation around nodes has no effect on the tree's topology (Figure 13.27).

There is only one correct phylogenetic tree that most accurately depicts the evolutionary history of a group of gene sequences, but inferring this tree from sequence data can be a challenging task. The complexity of the problem is revealed by considering the total number of different trees that can be formed from a random set of

Figure 13.27 Phylogenetic trees and their interpretation. Three equivalent versions of the same phylogenetic tree are shown. The only difference between the trees is that their nodes have been rotated at the points indicated by red circles. The vertical position of species is different between the trees, but the pattern of ancestry (the nodes shared by each species) remains unchanged.

1. The first step in making a tree is to align sequences.

2. A distance matrix is calculated from the number of sequence differences.

3. The tree is constructed by adding nodes to join lineages that have the fewest differences.

Figure 13.28 Building phylogenetic trees. The number of nucleotide differences between gene sequences can be used to build a phylogenetic tree. In the sequence alignment (a) we can count the number of differences between each pair of sequences to build a distance matrix (b). This distance matrix can be used to build a tree (c) where the cumulative lengths of the horizontal branches (labeled with a red "1") between any two species in the tree are proportional to the number of nucleotide differences between these species.

sequences. For example, only three possible trees can be drawn for any four arbitrary sequences. But if the number of sequences is doubled to eight, now 10,395 trees are possible. This complexity continues to expand exponentially such that 2×10^{182} different trees can be drawn to represent 100 arbitrary sequences. Phylogenetic analysis uses molecular sequence data in an attempt to identify the one correct tree that accurately represents the evolutionary history of a set of sequences.

A variety of methods are available for inferring phylogenetic trees from molecular sequence data. The structure of a phylogenetic tree is inferred by applying either an *algorithm* or some set of *optimality criteria*. An algorithm is a programmed series of steps designed to construct a single tree (Figure 13.28). Algorithms used to build phylogenetic trees include the *unweighted pair group method with arithmetic mean* (UPGMA) and the *neighbor-joining method*. Alternatively, phylogenetic methods that employ optimality criteria include *parsimony*, *maximum likelihood*, and *Bayesian* analyses. These latter methods evaluate many possible trees and select the one tree that has the best optimality score, that is, they select the tree that best fits the sequence data given a discrete model of molecular evolution. Optimality scores are calculated on the basis of evolutionary models that describe how molecular sequences change over time. For example, evolutionary models can account for variation in substitution rates and base frequencies between sequence positions.

Limitations of Phylogenetic Trees

Molecular phylogeny provides powerful insights into evolutionary history, but it is important to consider the limitations of building and interpreting phylogenetic trees. For example, it can be difficult to choose the true tree based on available sequence data if several different trees fit the data equally well. *Bootstrapping*, a statistical method in which phylogenetic information is resampled at random, is an approach used to deal with uncertainty in phylogenetic trees. Bootstrap values indicate the *percentage of the time* that a given node

in a phylogenetic tree is supported by the sequence data. High bootstrap values indicate that a node in the tree is likely to be correct, while low bootstrap values indicate that the placement of a node cannot be accurately determined given the available sequence data.

Homoplasy, also known as *convergent evolution*, occurs when organisms share a trait that was not inherited from a common ancestor. An example is the evolution of wings in insects and birds. These traits evolved separately and do not indicate that a winged ancestor was shared among insects and birds. Homoplasy occurs in molecular sequences as well, when similar sequence positions result from recurrent mutation rather than inheritance from a common ancestor (Figure 13.29a). The problem of homoplasy in molecular phylogeny then increases in proportion to evolutionary time (Figure 13.29b). As a result of homoplasy, the reconstruction of accurate phylogenetic trees gets more difficult when sequence divergence between organisms is very high.

The prevalence of horizontal gene transfer (Section 13.9 and Chapter 9) also creates complications when considering the evolutionary history of microorganisms. When the sequence of a gene is used to infer the phylogeny of an organism, it must be assumed that the gene is inherited in a *vertical* fashion—from mother to

daughter—throughout the evolutionary history of the organism. The *horizontal* exchange of genes between unrelated organisms violates this assumption (Figure 13.30). Hence, it is important to consider the difference between a *gene phylogeny*, which depicts the evolutionary history of an individual gene, and an *organismal phylogeny*, which depicts the evolutionary history of the cell.

In general, genes encoding SSU rRNAs appear to be transferred horizontally at very low frequencies, and rRNA gene phylogenies agree largely with those prepared from other genes that encode genetic informational functions. Thus, SSU rRNA gene sequences are generally considered to provide an accurate record of organismal phylogeny. Nevertheless, many microbial genomes contain genes that have been acquired by horizontal gene transfer at some point in their evolutionary history, and this has important implications for microbial evolution that cannot be adequately assessed by analyzing only a single gene, even one as phylogenetically informative as that encoding SSU rRNA.

Check Your Understanding

- Why are small subunit ribosomal RNA (SSU rRNA) genes commonly used in microbial phylogeny?
- How does bootstrapping aid in choosing a true phylogenetic tree?
- Why is sequence alignment critical to phylogenetic analysis?

Recurrent mutation can erase evolutionary information, causing sequence differences to underestimate true distances.

Four differences are observed between sequences 1 and 4.

Only one difference is observed between sequences 1 and 4.

(a)

(b)

Figure 13.29 The problem of homoplasy due to recurrent mutation. It is possible for recurrent mutation to obscure the true number of mutations that have occurred since a pair of sequences have shared a common ancestor. (a) Two series of mutations during the evolution of a gene sequence are compared. On the left side, the number of mutations is equal to the number observed between species 1 and 4. However, if there is recurrent mutation (right side), the number of mutations observed between species 1 and 4 can be less than the number that actually occurred. (b) The likelihood of recurrent mutation increases as more and more mutations accumulate over time.

13.12 Microbial Systematics

Microbial systematics is the branch of microbiology concerned with naming and classifying microorganisms, describing their traits, and investigating their evolutionary histories. *Nomenclature*—the naming of organisms—follows the **binomial system** devised by the Swedish medical doctor and botanist Carl Linnaeus in which species are given *genus names* and *species epithets*. The names are Latin or Latinized Greek derivations in which the genus name is a noun and the species epithet an adjective describing some key property of the organism or the habitat from which the organism was obtained. Occasionally, a species epithet will be derived from the last name of a scientist who has made major contributions to the study of a particular group of organisms.

Taxonomy is the classification of organisms into groups of similar organisms. Individual microbial strains are classified into species, species classified into genera, genera into families, families into orders, orders into classes, classes into phyla, and phyla into domains (Table 13.1). By classifying organisms into groups and naming them, we order the natural microbial world and make it possible to communicate effectively about all aspects of particular organisms, including their behavior, ecology, physiology, pathogenesis, and evolutionary relationships.

Species are the fundamental units of biological diversity, and how we distinguish and classify species in microbiology greatly affects our ability to explain and assess the diversity of the microbial world. For the purpose of microbial systematics, a microbial species is a taxonomic category that defines a population of individuals that (1) is monophyletic (descended from a common ancestor, see next subsection), (2) is genomically coherent, (3) is phenotypically coherent, and (4) can be clearly differentiated from other species. The description of microbial species employs a *polyphasic approach*, using many different methods in combination,

Figure 13.30 Horizontal gene transfer. The horizontal transfer of a gene will cause it to have a different evolutionary history from the rest of the genome. (a) Genes are transferred horizontally between distantly related microorganisms. Colors are used to match microorganisms with their genomes. (b) As a result of the horizontal transfer events in part a, different phylogenetic trees for gene 1, gene 2, and gene 3 are obtained. Only the gene tree for gene 1, which was not transferred, remains congruent with the organismal phylogeny.

to identify, describe, and name species of *Bacteria* and *Archaea*. In this section we describe methods commonly used for characterizing species of *Bacteria* and *Archaea*.

Phylogenetic Analyses

A microbial species should be **monophyletic**, that is, the strains composing the species should all share a recent common ancestor to the exclusion of other species. The phylogenetic relationships of microorganisms are typically determined by analyzing their SSU rRNA gene sequences (Section 13.11). Phylogenetic trees will show that the SSU rRNA gene sequences from strains of a distinct species will all form a coherent group that shares a recent common ancestor to the exclusion of strains of any other species. In addition, SSU rRNA genes from strains of the same species typically have greater than 98.6% sequence similarity, whereas SSU rRNA genes from different species typically have less than 97% sequence similarity (Figure 13.31).

SSU rRNA gene sequence similarity can also be useful in classification at higher taxonomic ranks. While there are no established cut-offs or formal criteria used to define higher taxonomic ranks, taxonomic ranks above species generally correlate with SSU rRNA gene sequence similarity. For example, the median SSU rRNA gene sequence similarity between strains of the same group is approximately 95% at the genus level, 92% for family, 89% for order, 86% for class, and 83% for phylum.

Multilocus sequence analysis (MLSA) can be used in addition to SSU rRNA gene sequence analysis to determine phylogenetic relationships. SSU rRNA gene sequences are highly conserved, and

while they provide valuable phylogenetic information, they are not always useful for distinguishing closely related species. By contrast, other highly conserved genes, such as *recA*, which encodes a recombinase protein (◀ Sections 9.4 and 9.5 and Figures 9.10 and 9.12), and *gyrB*, which encodes DNA gyrase (◀ Sections 6.1 and 6.4 and Figures 6.4 and 6.16), can be useful for distinguishing bacteria at the species level, and techniques are available to examine them collectively. The DNA sequences of protein-encoding genes accumulate mutations more rapidly than rRNA genes and thus their sequences can often distinguish prokaryotic species that cannot be resolved by rRNA gene sequence analyses alone (Figure 13.32). MLSA multigene analyses generally employ a minimum of four genes but can include more than a thousand genes if genome data are available. These genes can be analyzed independently, or they can be linked into a single alignment and analyzed as a unit to produce a single phylogenetic tree (Figure 13.32).

Genomic Analyses

The use of *entire genomes* for the identification and description of bacteria is becoming increasingly common as DNA sequencing capacities improve and costs decline (◀ Section 10.2). A wide range of sequence analyses are performed on whole genomes, thereby providing insights into microbial physiology and microbial evolution. Comparative analyses of gene content (presence or absence of genes), *synteny* (the order of genes in the genome), and genome G + C content (Section 13.9) provide powerful insights into evolutionary relationships between strains. Whole genome sequences can

TABLE 13.1 Taxonomic hierarchy for the purple sulfur bacterium <i>Allochromatium warmingii</i>			
Taxon	Name	Properties	Confirmed by
Domain	<i>Bacteria</i>	Bacterial cells; rRNA gene sequences typical of <i>Bacteria</i>	Microscopy; 16S rRNA gene sequence analysis; presence of unique biomarkers, for example, peptidoglycan
Phylum	<i>Proteobacteria</i>	rRNA gene sequence typical of <i>Proteobacteria</i>	16S rRNA gene sequence analysis
Class	<i>Gammaproteobacteria</i>	Gram-negative bacteria; rRNA sequence typical of <i>Gammaproteobacteria</i>	Gram-staining, microscopy
Order	<i>Chromatiales</i>	Phototrophic purple bacteria	Characteristic pigments ► Figures 14.6, 14.7, and 14.13)
Family	<i>Chromatiaceae</i>	Purple sulfur bacteria	Ability to oxidize H ₂ S and store S ⁰ within cells; microscopic observation of S ⁰ (see photo); 16S rRNA gene sequence
Genus	<i>Allochromatium</i>	Rod-shaped purple sulfur bacteria; <95% 16S rRNA gene sequence identity with other genera	Microscopy (see photo)
Species	<i>warmingii</i>	Cells 3.5–4.0 μm × 5–11 μm; storage of sulfur mainly in poles of cell (see photo); <97% 16S rRNA gene sequence identity with other species	Cell size measured microscopically with a micrometer; observation of polar position of S ⁰ globules in cells (see photo); 16S rRNA gene sequence

Sulfur (S⁰) globules

Norbert Plönnig

also be used for metabolic reconstruction to determine the potential physiological characteristics of a given strain.

Several methods in comparative genomics and population genomics have been developed for use in systematic analyses. In particular, metrics of overall genome relatedness can be calculated by determining sequence similarity across the entire genome. **Average nucleotide identity (ANI)** is the most commonly used metric for estimating overall genome relatedness between a pair of organisms. To do this, a computer breaks a genome sequence

into fragments about 1000 bp in length. Each fragment is then aligned to its orthologous sequence in a second genome and the average nucleotide identity between the two genomes calculated. Genomes from strains of the same species typically have greater than 96% ANI, and genomes from different species typically have less than 93% ANI (Figure 13.31).

Phenotypic Analyses

The observable characteristics—the **phenotype**—of a bacterium provide many traits that can be used to differentiate species. Typically, several phenotypic traits are determined routinely when describing a new microorganism. These phenotypic results are then compared to the phenotypes of organisms that have been described previously. The phenotypic traits that are determined will depend on the type of organism being described. For example, in applied situations, such as clinical diagnostic microbiology, where timely identification is important, a well-defined subset of traits can be tested to rapidly discriminate between different types of microorganisms. **Table 13.2** lists general categories and examples of some phenotypic traits used in identifications and species descriptions.

Phenotypic characteristics of a given organism can be highly dependent on growth conditions, and the phenotype of an organism observed in the laboratory may not be the same as that expressed in the natural environment. Thus, care must be taken in using phenotypic characteristics in systematic analyses. In addition, the value of different phenotypic characteristics for reaching a firm systematics conclusion can vary with the taxonomic groups being examined.

Figure 13.31 Classification of bacterial and archaeal species. Species identification is facilitated by performing pairwise comparison of 16S rRNA similarity and average nucleotide identity (ANI) between strains. Strains with >98.6% 16S rRNA similarity and >96% ANI typically belong to the same species. Strains with 97–98.6% 16S rRNA similarity and 93–96% ANI possibly belong to the same species, but further tests are needed to confirm identity. Strains with <97% 16S rRNA similarity and <93% ANI are highly unlikely to belong to the same species.

Figure 13.32 Multilocus sequence analysis (MLSA). Phylogenies are shown for species in the genus *Photobacterium*. (a) 16S rRNA gene tree, showing the species to be poorly resolved. (b) MLSA based on the combined analysis of the 16S rRNA gene and *gyrB* and *luxABFE* genes in 21 isolates of three *Photobacterium* species. MLSA clearly resolves the strains into three distinct species, *P. phosphoreum*, *P. iliopiscarium*, and *P. kishitanii*. The scale bar indicates the branch length equal to a total of 50 nucleotide changes. The type strain of each species is listed in bold. (All abbreviations are part of strain designations.) Phylogenetic analyses courtesy of Tory Hendy and Paul V. Dunlap, University of Michigan.

The Description of New Species

When a newly discovered strain of *Bacteria* or *Archaea* is thought to be unique, a decision must be made as to whether it is sufficiently different from established taxa to be described as a new taxon. The creation of new taxa of *Bacteria* and *Archaea* must follow the rules described in the *International Code of Nomenclature of Prokaryotes* (the Prokaryotic Code). To achieve formal validation of taxonomic standing as a new genus or species, a detailed description of the organism's characteristics and distinguishing traits, along with its proposed name, must be published in a specialized peer-reviewed journal, and viable cultures of the organism must be deposited in at least two international culture collections. Most new taxa are described in the *International Journal of Systematic and Evolutionary Microbiology* (IJSEM), the publication of record for the nomenclature of *Bacteria* and *Archaea*. Two websites provide listings of valid, approved bacterial names: List of Prokaryotic Names with Standing in Nomenclature (<http://www.bacterio.net>), and Prokaryotic Nomenclature Up-to-Date (<http://www.dsmz.de>).

Microbial culture collections play an important role in protecting microbial biodiversity, just as museums do in preserving plant and animal specimens for future study. Culture collections store microorganisms as *viable cultures*, typically frozen or in a freeze-dried state, and distribute cultures to qualified scientists who wish to study them. These storage methods maintain the cells indefinitely in a living state and prevent genetic changes that might occur if the

organisms were continually subcultured. Culture collections also serve as repositories for *type strains*. When a new species of bacteria is described in a scientific journal, a strain is designated as the **type strain** and serves as the nomenclatural type of the taxon for future taxonomic comparison with other strains of that species. Major international culture collections exist in the United States (ATCC), Germany (DSMZ), Japan (JCM Riken), and several other countries. Each collection has a website linked to its acronym from which its holdings can be searched.

It is possible to use molecular and genomic techniques (Chapters 10 and 19) to characterize the phenotypic and genotypic characteristics of microorganisms without the need for the cultivation of an isolated strain. However, in the absence of an isolate that can be deposited in two international culture collections, it is not yet possible to validly name a new species of microorganism under the Prokaryotic Code. However, when an organism is well characterized but not yet obtained in pure culture, a provisional taxonomic name can be applied. The moniker *Candidatus* is appended to candidate taxonomic ranks. For example, "*Candidatus Pelagibacter ubique*" is a globally widespread and well-characterized marine bacterium that is difficult to grow in laboratory media (► Section 20.12) and so has not been formally named under the Prokaryotic Code. By contrast, the bacterium "*Candidatus Heliomonas lunata*" can be grown in laboratory culture but the culture is not pure, so this bacterium also retains *Candidatus* status.

TABLE 13.2 Some phenotypic characteristics of taxonomic value

Category	Characteristics
Morphology	Colony morphology; Gram reaction; cell size and shape; pattern of flagellation; presence of spores, inclusion bodies (e.g., PHB, ^a glycogen, or polyphosphate granules, gas vesicles, magnetosomes); capsules, S-layers, or slime layers; stalks or appendages; fruiting body formation
Motility	Nonmotile; gliding motility; swimming (flagellar) motility; swarming; motile by gas vesicles
Metabolism	Mechanism of energy conservation (phototroph, chemoorganotroph, chemolithotroph); utilization of individual carbon, nitrogen, or sulfur compounds; fermentation of sugars; nitrogen fixation; growth factor requirements
Physiology	Temperature, pH, and salt ranges for growth; response to oxygen (aerobic, facultative, anaerobic); presence of catalase or oxidase; production of extracellular enzymes
Cell lipid chemistry	Fatty acids; polar lipids; respiratory quinones
Cell wall chemistry	Presence or absence of peptidoglycan; amino acid composition of cross-links; presence or absence of cross-link interbridge
Other traits	Pigments; luminescence; antibiotic sensitivity; serotype; production of unique compounds, for example, antibiotics

^aPHB, poly-β-hydroxybutyric acid (◀ Section 2.7).

The classification system most widely accepted by microbiologists is that of *Bergey's Manual of Systematics of Archaea and Bacteria*, a major taxonomic treatment of *Bacteria* and *Archaea* that has served microbiologists since 1923 as a compendium of information on all recognized prokaryotic species. Each chapter, written by experts, contains tables, photos, figures, and other systematic information useful for identification purposes. A second major source describing the physiology, ecology, phylogeny, enrichment, isolation, and cultivation of *Bacteria* and *Archaea* is *The Prokaryotes*. This work is available online by subscription through university libraries. Collectively, *Bergey's Manual* and *The Prokaryotes* offer microbiologists both the concepts and the details of the biology of *Bacteria* and *Archaea* as we know them today and are the primary resources for microbiologists characterizing newly isolated organisms.

How Many Species of *Bacteria* and *Archaea* Exist?

The result of nearly 4 billion years of evolution is the microbial world we see today (Figure 13.9). Microbial taxonomists agree that no firm estimate of the number of bacterial and archaeal species can be given at present. However, they also agree that in the final analysis, this number will be very large. The diversity of bacterial and archaeal species on Earth is unquestionably higher than that of all plant and animal species combined, and the total species numbers of *Bacteria* and *Archaea* are likely several orders of magnitude higher than the 14,000 species that have been characterized to date.

Every environment on Earth contains a diverse community of microorganisms. For example, analyses of environmental SSU rRNA gene sequences (▶ Section 19.6) suggest that over 14,000 different species can coexist in a single gram of soil! Since 1977, more than 3.3 million SSU rRNA sequences have been deposited in international databases such as GenBank and used to characterize the vast diversity of the microbial world. These SSU rRNA sequences encompass more than 225,000 *operational taxonomic units* (OTUs), species-like units of diversity which are defined at a 97% sequence similarity threshold (Figure 13.31). The Ribosomal Database Project (RDP; <http://rdp.cme.msu.edu>) contains an ever-growing collection of these sequences and provides computational programs for their analysis and for the construction of phylogenetic trees.

While we do not yet know the extent of biodiversity of microbial life, we do know that nearly all plant and animal species have microbiomes (Chapter 23) that contain countless numbers of unique microbes. Thus, microorganisms are not only the oldest but also unquestionably the most diverse forms of life on our planet. We will see this diversity in action over the next five chapters.

Check Your Understanding

- What are some key criteria used to determine whether two strains belong to the same species?
- What is average nucleotide identity and how is it calculated?
- What is the process for describing and naming a new species of bacteria?

Go to **Mastering Microbiology** for videos, animations, practice tests, and more.

CHAPTER REVIEW

I • Early Earth and the Origin and Diversification of Life

- 13.1** Planet Earth is about 4.5 billion years old. After its formation, Earth was hot and sterile. Gradual cooling of the planet allowed formation of liquid water, a requirement for the origin of life. The earliest evidence of life comes from isotopic analysis of ancient sedimentary rocks and zircon minerals

indicating that life was present on Earth by 3.7–4.1 billion years ago.

Q What is LUCA, and what is a plausible explanation for the origin of cellular life?

- 13.2** In rocks 3.5 billion years old or younger, microbial formations called stromatolites are abundant and show extensive microbial diversification. The evolution of

oxygenic photosynthesis caused O₂ to accumulate 2.4 billion years ago, eventually leading to the formation of banded iron formations, the ozone shield, and an oxygenated atmosphere, which set the stage for rapid diversification of metabolic types and the evolution of multicellularity.

Q Why was the origin of cyanobacteria of such importance to the evolution of life on Earth?

- 13.3** Ribosomal RNA genes have been used to construct a universal tree of life revealing that life on Earth evolved in three major directions, forming the domains *Bacteria*, *Archaea*, and *Eukarya*. The universal tree of life shows that the domains *Bacteria* and *Archaea* diverged billions of years ago, and that *Eukarya* split from *Archaea* later in the history of life.

Q What is the three-domain concept of the tree of life? How was the tree of life constructed?

- 13.4** The eukaryotic cell developed from endosymbiotic events. The modern eukaryotic cell is a chimera with genes and characteristics from both *Bacteria* and *Archaea*. 16S rRNA sequence analyses indicate the ancestors of mitochondria are found in the phylum *Proteobacteria* and those of chloroplasts are found in the phylum *Cyanobacteria*.

Q What is the endosymbiotic theory for the origin of mitochondria and chloroplasts? What evidence supports this theory?

- 13.5** Viruses lack universally conserved genes and so cannot be placed on the universal tree of life. Viruses might have evolved many times from rogue mobile genetic elements such as gene transfer agents, or they might have a single origin as remnants of pre-cellular life from the RNA world.

Q All viruses protect their nucleic acid using a capsid shell composed of protein. Provide a hypothesis to explain the evolution of capsid proteins.

II • Mechanisms of Microbial Evolution

- 13.6** Evolution is defined as a change in allele frequencies in a population of organisms over time, resulting in descent with modification. New alleles are created through the processes of mutation and recombination. Mutations occur at random and most mutations are neutral or deleterious, but some are beneficial. Natural selection and genetic drift are two mechanisms that cause allele frequencies to change in a population over time.

Q What is fitness? To what degree does fitness depend on the environment in which organisms live?

- 13.7** Experimental evolution uses microbial systems to investigate evolution in the laboratory. Mutations occur at random, but those that improve fitness will increase in frequency in a population of cells. Environmental conditions dictate whether mutations cause a change in fitness. Mutations may cause a gain, loss, change, or no change in function.

Q Do *Rhodobacter* pigment mutations occur at the same frequency in the light and in the dark? In the LTEE, do you expect that citrate-using mutants would still have occurred if citrate had never been present in the growth medium?

- 13.8** A gene family contains a group of homologs that have all descended from the same ancestral gene. Homologs are orthologs if they have same function or paralogs if they have evolved different functions. Paralogs often evolve as a result of gene duplication. Deletion mutations are common in microbial genomes, and they cause the rapid elimination of genetic material that is unnecessary or redundant in function.

Q Explain how deletion mutations can increase fitness. Explain how duplication mutations can promote the evolution of new gene functions.

- 13.9** Horizontal gene transfer allows genes to be exchanged between cells irrespective of species boundaries. The mobilome is the portion of the genome that contains mobile genetic elements that facilitate horizontal gene exchange and chromosomal rearrangements. The mobilome includes plasmids, viruses, transposons, integrons, and insertion sequences.

Q How can comparative genomics help identify horizontal gene transfer?

- 13.10** Microbial genomes are dynamic, and genome size and gene content can vary considerably between strains of a species. The core genome is defined as the set of all genes shared by a species, while the pan genome is defined as the core genome plus genes whose presence varies among strains of a species. Many bacteria contain chromosomal islands, large clusters of genes acquired by horizontal gene transfer, that encode specialized functions such as virulence (pathogenicity islands).

Q How can microbial genomes vary extensively between strains of a single microbial species?

III • Microbial Phylogeny and Systematics

- 13.11** Molecular sequences accumulate random mutations over time, and molecular phylogenetic analysis examines differences in molecular sequences to determine the evolutionary history of life. A phylogenetic tree is a diagram that depicts the evolutionary history of a set of genes or organisms.

Q How can horizontal gene transfer (HGT) lead to phylogenetic incongruence? How can this be overcome?

- 13.12** Systematics is the study of the diversity and relationships of living organisms. Species of *Bacteria* and *Archaea* are classified using phylogenetic, genomic, and phenotypic information. Strains of the same species are monophyletic, typically have >98.6% SSU rRNA sequence similarity and >96% average nucleotide identity across their genomes, and are expected to share a coherent set of phenotypic traits.

Q Is it possible to provide a formal name for a microorganism that has not been cultivated in isolation? How might you attempt to describe and name such a species?

APPLICATION QUESTIONS

1. Compare and contrast the physical and chemical conditions on Earth at the time life first arose with conditions today. From a physiological standpoint, discuss at least two reasons why *animals* could not have existed on early Earth. In what ways has microbial metabolism altered Earth's biosphere? How might life on Earth be different if oxygenic photosynthesis had not evolved?
2. For the following sequences, construct the phylogenetic tree that best depicts their evolutionary relationships (assume that the sequences are aligned).

Taxon 1: GTTCCCTA

Taxon 2: GTTCGCTA

Taxon 3: GATAGCCA

Taxon 4: GTTCGCTA

3. Imagine that you are given several bacterial strains from a non-native plant species in your country. How could you infer their evolutionary history in relation to bacterial strains from the same plant species found at their native habitats?

CHAPTER GLOSSARY

Allele a sequence variant of a given gene

Archaea a domain of life consisting of microorganisms that have prokaryotic cell structure and are distinct from *Bacteria*

Average nucleotide identity (ANI)

a genome-wide measure of genetic similarity between two microorganisms based on aligning all orthologous gene pairs across the two genomes and determining the percentage of matching nucleotides (see also *orthologs*)

Bacteria a domain of life consisting of microorganisms that have prokaryotic cell structure and are distinct from *Archaea*

Banded iron formation iron oxide-rich ancient sedimentary rocks containing zones of oxidized iron (Fe^{3+}) formed by oxidation of Fe^{2+}

Binomial system the system devised by the Swedish scientist Carl Linnaeus for naming living organisms in which an organism is given a genus name and a species epithet

Chromosomal island a chromosome region of foreign origin containing a cluster of genes that work together to confer upon the cell a particular trait such as virulence or symbiosis

Core genome those genes shared by all strains of a species

Endosymbiotic theory the idea that mitochondria and chloroplasts originated from *Bacteria*

Eukarya a domain of life consisting of organisms that have eukaryotic cell structure; includes algae, protists, fungi, slime molds, plants, and animals

Evolution a change over time in gene sequence and frequency within a population of organisms, resulting in descent with modification

Evolutionary selection a process that results in a change in allele frequencies in a population when individuals that are favored in a given environment are able to produce more offspring and make a greater contribution to the gene content of future generations

Fitness the capacity of an organism to survive and reproduce in a given environment as compared to that of competing organisms

Gene family genes related in sequence to each other because of common evolutionary origin

Genetic drift a process that results in a change in allele frequencies in a population as a result of random changes in the number of offspring from each individual over time

Homologs genes that were inherited from a shared ancestor; includes both orthologs and paralogs

Homoplasy when two organisms have the same trait as a result of recurrent mutation or convergent evolution

Horizontal gene transfer the unidirectional transfer of genes between cells through a process uncoupled from reproduction

Mobilome the mobile genetic elements in a genome

Molecular clock a DNA sequence, such as a gene for rRNA, that can be used as a comparative temporal measure of evolutionary divergence

Monophyletic in phylogeny, a group descended from a single shared ancestor

Multilocus sequence analysis (MLSA) phylogenetic analysis of microorganisms performed using multiple different genes

Mutation a heritable change in the base sequence of the genome of an organism

Orthologs genes that are homologous (that is, they are descended from a common ancestor) and share the same function (see also *paralogs*)

Pan genome the totality of the genes present in the different strains of a species

Paralogs genes that are homologous (that is, they are descended from a common ancestor) but which have diverged to have different functions; typically, paralogous genes are the result of gene duplication (see also *orthologs*)

Pathogenicity island a bacterial chromosome region of foreign origin that contains clustered genes for virulence

Phenotype the observable characteristics of an organism

Phylogenetic tree a diagram that depicts the evolutionary history of an organism; consists of nodes and branches

Phylogeny evolutionary history of organisms

Phylum a major lineage of organisms in one of the three domains of life

Recombination a resorting or rearrangement of DNA fragments resulting in a new sequence

Ribosomal RNA (rRNA) the types of RNA found in the ribosome; some participate actively in protein synthesis

Sequence alignment the insertion of gaps into a set of molecular sequences organized in rows so that homologous positions are organized in vertical columns. Alignment is necessary prior to phylogenetic analysis because deletion and insertion mutations cause variations in the length of molecular sequences

16S rRNA the type of SSU rRNA found in *Bacteria* and *Archaea*; its eukaryotic counterpart is 18S rRNA (see also *SSU rRNA*)

Species defined in microbiology as a collection of strains that all share the same major properties and differ in one or more significant properties from other collections of strains; defined phylogenetically as a monophyletic, exclusive group based on DNA sequence

SSU rRNA (small subunit rRNA) the rRNA molecule found in the small subunit of the ribosome, comprised of 16S rRNA, which is present in the 30S ribosomal subunit of *Bacteria* and *Archaea*, or its orthologous counterpart 18S rRNA, which is present in the 40S ribosomal subunit of *Eukarya*. SSU rRNA genes are conserved in all forms of cellular life, and this gene is often used in phylogenetic analysis of microorganisms

Stromatolite a laminated microbial mat that can become fossilized and is typically built from layers of filamentous microorganisms

Systematics the study of the diversity of organisms and their relationships; includes taxonomy and phylogeny

Taxonomy the science of identification, classification, and nomenclature

Type strain the strain chosen to represent the nomenclatural type of a species; type strains are deposited in microbial culture collections and are used to represent the typical characteristics of their species

Universal tree of life a phylogenetic tree that shows the positions of representatives of all domains of cellular life

MICROBIOLOGYNOW

Ferretting Out the Peculiar Life of Iron Bacteria

Life requires the movement of electrons from one place to another, and microbes have found many different ways to accomplish this. Many iron-oxidizing bacteria are autotrophic chemolithotrophs that conserve energy by oxidizing Fe^{2+} and transporting electrons to an electron acceptor such as O_2 . Fe^{2+} is present in anoxic groundwater, and the “iron bacteria” grow where this ferrous-rich water reaches the oxic surface. However, aerobic iron bacteria face an unusual challenge because when reduced iron meets O_2 , it spontaneously oxidizes to form rust. To survive, iron bacteria must outcompete this abiotic process. Another challenge is that iron bacteria form iron oxide minerals as waste products, and as they grow, they risk becoming entombed within a metallic crust of their own making.

Iron bacteria have evolved elegant strategies for overcoming these obstacles. They have specialized mechanisms for donating electrons to extracellular electron acceptors, and this prevents iron oxides from forming within cells. In addition, they catalyze iron biomineralization, forming stalks

and sheaths that are extruded away from the cell. The photos here show cells of the iron bacterium *Leptothrix ochracea* forming a microbial mat in a spring in Spruce Point, Maine (USA). In these fluorescence micrographs, the cells (about 5 μm long) are stained yellow and occur only at the tips of hollow iron oxide sheaths, stained red. The aerobic oxidation of iron provides only a very small amount of energy and because of this, iron bacteria leave long empty iron oxide sheaths as they grow. The cells sense and constantly move toward O_2 , meaning that sheath production functions almost as a form of motility that allows *L. ochracea* to position itself effectively in response to gradients of Fe^{2+} and O_2 .

Microbes are often defined by their metabolic properties, and to understand bacteria like *L. ochracea*, we must first understand their metabolism.

Source: Chan, C.S., et al. 2016. The architecture of iron microbial mats reflects the adaptation of chemolithotrophic iron oxidation in freshwater and marine environments. *Front. Microbiol.* 7: 796.

A major theme of microbiology is the great *phylogenetic* diversity of microbial life on Earth. We will explore this microbial diversity in the following four chapters. In this chapter we focus on the *metabolic* diversity of microorganisms, with special emphasis on the processes and mechanisms that underlie this diversity. Metabolism provides one framework we can use to make sense of microbial diversity. In the following chapters, we will see that microbial diversity can be understood in terms of metabolic diversity, ecological diversity, and phylogenetic diversity.

I • Introduction to Metabolic Diversity

All cells conserve energy, obtain reducing power, and achieve a redox balance by carrying out oxidation–reduction reactions. Metabolic pathways are modular and often reversible, facilitating the evolution of metabolic diversity through horizontal gene transfer.

While microbial metabolism is amazingly diverse, all microbes follow the same basic metabolic principles. These principles were introduced in Chapter 3, and we revisit them now and expand upon them to see how they apply to diverse metabolic types. In all forms of metabolism, energy is conserved and reducing power is obtained during catabolic reactions (◀ Figure 3.1), and cells grow by coupling this energy to anabolic (biosynthetic) reactions such as CO₂ fixation. We begin our review of metabolic diversity by reviewing the mechanisms of energy conservation and their relationship to redox reactions.

14.1 Foundational Principles of Metabolic Diversity: Energy and Redox

The diversity of metabolic types in the microbial world is tremendous, and these diverse organisms are essential to sustain our biosphere. In part, this diversity is driven by the modularity of metabolic reactions. Metabolic modularity facilitates the evolution of metabolic diversity by allowing the formation of new pathways from the horizontal transfer and modification of existing enzymes and pathways. For example, the components of electron transport allow for a tremendous diversity of respirations, most of which do not involve O₂ and are thus anaerobic respirations (Figure 14.1). By understanding the principles that underlie metabolism, we can move beyond the memorization of pathways as unique entities and instead learn to predict the metabolic needs of any organism we encounter in the microbial world.

All organisms need to **conserve energy** by converting chemical or light energy into ATP. They also need a source of **reducing power**, a source of highly electronegative electrons for performing redox reactions. Finally, they need to achieve **redox balance** by regenerating oxidized electron carriers (such as NAD⁺) through the use of an external electron acceptor (in respiration), or by recycling electrons back onto a metabolic intermediate and excreting them as fermentation products (in fermentation).

Conservation of Energy

All cells conserve energy by coupling a flow of electrons to the synthesis of ATP. Electron flow in the cell consists of a series of *redox*

Figure 14.1 Diversity of respiration reactions. The redox couples (right, yellow box) are arranged in order from most electronegative E_0' (top) to most electropositive E_0' (bottom), assuming neutral pH. An exergonic reaction results when an electron donor (left, green box) donates electrons to an electron acceptor from a more electropositive (lower) redox couple. See Figure 3.4 and Table 3.1 to compare how the energy yields of some of these anaerobic respirations vary. The E_0' of the Fe³⁺/Fe²⁺ couple at pH 2 is +0.77 V. NH₃ is shown to indicate its relative E_0' value as a donor. C_{org}, organic carbon compounds (glucose, ethanol, etc.).

reactions. Recall from Chapter 3 that redox reactions are reactions in which electrons are transferred from one substance (in one half reaction that *donates* electrons) to another substance (in a second half reaction that *accepts* electrons). The tendency of a substance to donate or accept electrons is defined by its reduction potential (E_0' , Figure 14.1; ◀ Figure 3.4 and Table 3.1). The farther apart the two half reactions are in terms of the E_0' of their redox couples, the greater the amount of energy available (◀ Figure 3.4).

Based on these simple principles governing redox reactions, a wide variety of organic or inorganic electron donors can be coupled to a wide variety of external electron acceptors (through respiration, Figure 14.1) or internal metabolic products (through fermentation), generating the tremendous diversity of metabolic options that exist in the microbial world. These reactions can support growth, provided sufficient energy is released for the production of ATP (-31.8 kJ/mol). Ultimately, the flow of electrons through redox reactions provides the energy for ATP synthesis by one of three mechanisms: *substrate-level phosphorylation*, *oxidative phosphorylation*, or *photophosphorylation* (Chapter 3). Chemotrophs conserve energy by the former two mechanisms while phototrophs use the latter. We will consider phototrophs in detail in Sections 14.3–14.6 and focus first on chemotrophic metabolism.

Chemotrophic Metabolism

Chemotrophic organisms can conserve energy through either fermentation or respiration. **Fermentation** does not require an external electron acceptor and ATP is generated primarily by substrate-level phosphorylation, with electron balance obtained by reducing metabolic intermediates that are then excreted as fermentation products (◀ Section 3.7). **Respiration**, by contrast, requires an external electron acceptor, and ATP is generated by oxidative phosphorylation resulting from electron transport reactions that generate a proton motive force (pmf); the enzyme complex ATP synthase harnesses this force to make ATP (◀ Section 3.9). Chemolithotrophs are chemotrophic organisms that use *inorganic* electron donors in respiration reactions (Table 14.1). Note in Table 14.1 how the energy yield of each reaction shown is determined by the $\Delta E_0'$ of its redox couples.

Respiration can occur under both oxic and anoxic conditions. **Anaerobic respirations** are those whose electron acceptors are other

than O_2 . From Figure 14.1 we can see that almost any half reaction can serve as an electron acceptor if coupled with a sufficiently electronegative electron donor. Because the O_2/H_2O couple is so electropositive, more energy is typically available from aerobic respiration than from anaerobic respiration. Therefore, for any given electron donor, aerobic organisms will always conserve more energy—and will therefore outcompete—anaerobic organisms. However, because O_2 is such a good electron acceptor, and because it is poorly soluble in water, it is consumed rapidly in poorly mixed environments. Thus, anoxic habitats and anaerobic organisms are widespread in nature.

Reducing Power and Redox Balance

The conservation of energy on its own is not sufficient to support life. Cells also need a source of reducing power for biosynthesis and need to achieve redox balance by balancing electron flow within the cell. The reducing power required for biosynthetic reactions is typically in the form of low-potential electron carriers such as NAD(P)H ($E_0' = -0.32$ V) or reduced ferredoxin (Fd_{red} , $E_0' = -0.37$ to -0.50 V). In the case of most chemoorganotrophs, this reducing power is readily generated during the oxidation of reduced organic molecules (◀ Sections 3.6 and 3.7). The challenge for chemoorganotrophs is managing their redox balance; that is, they need a way to export electrons from the cell in order to regenerate the oxidized NAD(P)⁺ or Fd_{ox} they need for catabolic reactions. Chemoorganotrophs achieve redox balance by donating electrons to external electron acceptors (in respiration) or metabolic intermediates (in fermentation) that are reduced and excreted from the cell. In contrast, the problem for many chemolithotrophs and some phototrophs (◀ Section 3.11) is a lack of reducing power. Their electron donors (such as S^0 , H_2S , NH_3 , and the like) are unable to reduce the NAD(P)⁺ or Fd_{ox} they need for catabolic and biosynthetic reactions. Hence, these organisms must generate reducing power by coupling the endergonic reduction of these electron carriers to some other exergonic reaction.

Three mechanisms of energy coupling are known that can increase reducing power or achieve redox balance at the expense of energy. The first is by coupling a reaction directly to ATP hydrolysis; this requires a substantial energy expenditure by the cell and so is used

TABLE 14.1 Energy yields from the oxidation of various inorganic electron donors^a

Electron donor	Chemolithotrophic reaction	Group of chemolithotrophs	E_0' of couple (V)	$\Delta G^0'$ (kJ/reaction)	Number of electrons/reaction	$\Delta G^0'$ (kJ/2 e [−])
Phosphite ^b	$4\text{HPO}_3^{2-} + \text{SO}_4^{2-} + \text{H}^+ \rightarrow 4\text{HPO}_4^{2-} + \text{HS}^-$	Phosphite oxidizers	−0.69	−364	8	−91
Hydrogen ^b	$\text{H}_2 + \frac{1}{2}\text{O}_2 \rightarrow \text{H}_2\text{O}$	Hydrogen oxidizers	−0.42	−237.2	2	−237.2
Sulfide ^b	$\text{HS}^- + \text{H}^+ + \frac{1}{2}\text{O}_2 \rightarrow \text{S}^0 + \text{H}_2\text{O}$	Sulfide oxidizers	−0.27	−209.4	2	−209.4
Sulfur ^b	$\text{S}^0 + 1\frac{1}{2}\text{O}_2 + \text{H}_2\text{O} \rightarrow \text{SO}_4^{2-} + 2\text{H}^+$	Sulfur oxidizers	−0.20	−587.1	6	−195.7
Ammonia	$\text{NH}_3 + 1\frac{1}{2}\text{O}_2 \rightarrow \text{NO}_2^- + \text{H}^+ + \text{H}_2\text{O}$	Ammonia oxidizers	+0.34	−287.6	6	−95.9
Nitrite ^b	$\text{NO}_2^- + \frac{1}{2}\text{O}_2 \rightarrow \text{NO}_3^-$	Nitrite oxidizers	+0.43	−74.1	2	−74.1
Ferrous iron ^b	$\text{Fe}^{2+} + \text{H}^+ + \frac{1}{4}\text{O}_2 \rightarrow \text{Fe}^{3+} + \frac{1}{2}\text{H}_2\text{O}$	Iron oxidizers	+0.77	−32.9	1	−65.8

^aData are from G_f^0 values in Table 3.1 (or references therein) and Figure 3.4, and from bioenergetics calculations as described in Sections 3.2 and 3.3; E_0' values for Fe^{2+} are for pH 2, and others are for pH 7. At pH 7, the E_0' for the $\text{Fe}^{3+}/\text{Fe}^{2+}$ couple is about +0.2 V.

^bExcept for phosphite, all reactions are shown coupled to O_2 as electron acceptor. The only known phosphite oxidizer couples to SO_4^{2-} as electron acceptor. H_2 and most sulfur compounds can be oxidized anaerobically using one or more electron acceptors, and Fe^{2+} can be oxidized at neutral pH with NO_3^- as electron acceptor. For other chemolithotrophic reactions of sulfur compounds, see Table 14.2.

primarily by organisms that perform highly exergonic catabolic reactions. The second is **reverse electron transport** (◀ Section 3.11) wherein the endergonic reduction of NAD(P)^+ or Fd_{ox} is driven by dissipation of the pmf. For example, during electron transport, an NADH:quinone oxidoreductase (such as Complex I, ◀ Figure 3.19) can donate electrons to an oxidized quinone, an exergonic reaction that contributes to the formation of the pmf. However, during reverse electron transport, this enzyme runs in the reverse direction and transfers electrons from a reduced quinone to NAD^+ , an endergonic reaction driven by the pmf.

The third, and most energy-efficient, mechanism of energy coupling is flavin-based **electron bifurcation** (Figure 14.2). In electron bifurcation, the endergonic reduction of a low-potential electron acceptor such as Fd_{ox} is driven by the exergonic reduction of a higher-potential electron acceptor such as NAD^+ (Figure 14.2). Electron-bifurcating enzymes contain a flavin coenzyme. The flavin accepts two electrons at a time and donates one of these electrons in an exergonic reaction to a higher-potential electron acceptor (such as NAD^+) in order to drive the endergonic reduction of a lower-potential electron acceptor (such as Fd_{ox}) by the other electron (Figure 14.2). For example, Figure 14.2 depicts a bifurcation

reaction in which 2 NADH ($2 \times 2 \text{ e}^-$, $E_0' = -0.32 \text{ V}$) are oxidized to reduce one low-potential Fd_{ox} ($2 \times 1 \text{ e}^-$, $E_0' = -0.42 \text{ V}$) and one crotonyl-CoA ($2 \times 1 \text{ e}^-$, $E_0' = -0.01 \text{ V}$). Some electron-bifurcating systems are even reversible, resulting in electron *confurcation* (see Sections 14.12 and 14.17).

Flavin-based electron-bifurcating enzymes have two important functions. (1) They allow the cell to make a highly electronegative intermediate (such as Fd_{red}) that can drive difficult endergonic reductions and can also be used to conserve energy through pmf formation (see Sections 14.12, 14.15–14.17, and 14.19). (2) They can increase fermentative energy yields by allowing the cell to oxidize NADH to NAD^+ through H_2 production from Fd_{red} (see Sections 14.17, 14.19). Many obligate anaerobes use flavin-based electron bifurcation reactions, particularly those having very low energy yields such as fermenters, sulfate reducers, acetogens, and methanogens. We will learn about these processes later in this chapter.

Assimilative and Dissimilative Processes

While chemoorganotrophs often get nutrients from organic materials, many chemotrophs and phototrophs can assimilate nutrients by

Figure 14.2 The reaction scheme for flavin-based electron bifurcation. Many obligate anaerobes require reducing power in the form of reduced ferredoxin (Fd_{red}) or flavodoxin (Fld_{red}) to perform difficult reactions (such as CO_2 fixation), but lack electron donors sufficiently electronegative to reduce ferredoxin. In flavin-based electron bifurcation, two electrons from an electron donor (such as H_2) are transferred to a flavin (FAD), and one electron is used to reduce a favorable electron acceptor (such as NAD^+), making it possible to drive the second electron to an unfavorable electron acceptor (such as Fd_{ox}). The reaction can be reversed yielding *electron confurcation*, for example by organisms that need to achieve redox balance by driving the endergonic formation of H_2 from NADH .

reducing inorganic molecules such as N_2 , NO_3^- , SO_4^{2-} , and CO_2 . *Assimilative* processes are those processes used to assimilate inorganic nutrients into cell material. By contrast, *dissimilative* processes are those processes used to conserve energy.

Assimilative and dissimilative processes differ markedly. In assimilative metabolism, *energy is consumed* as nutrients are assimilated into cellular material, and so assimilatory reactions are performed only to acquire those nutrients needed to satisfy the biosynthetic needs of growing cells. Since assimilatory reactions contribute to biosynthesis, they require energy in the form of ATP and reducing power. By contrast, in dissimilative metabolism, *energy is conserved*, and this means that a large amount of the electron acceptor must be reduced and then excreted from the cell. Most microbes can perform a variety of assimilative reduction reactions, whereas dissimilative reduction reactions are the result of anaerobic respiration.

The most important assimilative process in the biosphere is CO_2 fixation performed by autotrophic organisms. A diversity of pathways for fixing CO_2 into cellular material exist, as we will see next, and by exploring how these pathways differ we will shed light on the evolutionary forces that have produced the vast metabolic diversity within the microbial world.

Check Your Understanding

- In a coupled reaction, how can you tell the electron donor half reaction from the electron acceptor half reaction?
- How does aerobic respiration differ from anaerobic respiration, and why does aerobic respiration repress anaerobic respiration?
- Describe the major differences between assimilative and dissimilative processes.

14.2 Autotrophic Pathways

An **autotroph** is an organism that can assimilate CO_2 into cell material. Many microbes are autotrophic, including virtually all phototrophs and chemolithotrophs. In all autotrophs, CO_2 fixation supplies carbon for the biosynthesis of cellular materials, and in phototrophs, CO_2 is also the ultimate electron acceptor for photosynthesis.

The evolutionary origin of CO_2 fixation likely occurred very soon after the origin of life when Earth was still anoxic. As a result, most CO_2 fixation pathways contain enzymes inhibited by O_2 . Pathways of CO_2 fixation often share some enzymes with catabolic pathways, revealing the modularity of enzyme systems. Indeed, the presence of shared metabolites between pathways for catabolism and CO_2 fixation create opportunities for some organisms to grow as **mixotrophs**, meaning that rather than growing as either a heterotroph or an autotroph, they exist on a continuum between heterotrophy and autotrophy depending on the opportunities available to them in their environments. We will also see, as is the case with the Calvin cycle, that enzymes that provide a strong evolutionary benefit are often shared between microorganisms by horizontal gene transfer.

The Calvin Cycle

The **Calvin cycle** (◀ Section 3.12) is the most widespread and globally important pathway for CO_2 fixation. The Calvin cycle is used by all oxygenic phototrophs (including cyanobacteria, algae, and plants),

most purple bacteria, and most aerobic chemolithotrophic bacteria (◀ Section 3.11). This wide distribution indicates that many microbes acquired Calvin cycle genes from horizontal gene transfer. The key enzyme of the Calvin cycle is the enzyme **RuBisCO**, which reduces CO_2 to the level of glyceraldehyde 3-phosphate (◀ Section 3.12). The Calvin cycle requires 12 NAD(P)H and 18 ATP to synthesize one molecule of fructose 6-phosphate from 6 CO_2 (◀ Figure 3.27).

Many bacteria that perform the Calvin cycle have **carboxysomes** (Figure 14.3), which are proteinaceous microcompartments and are the site of RuBisCO activity. RuBisCO has very low affinity for CO_2 and is inhibited by O_2 . This inhibition occurs because O_2 competes with CO_2 for access to the RuBisCO active site, resulting in a waste of reducing power and decreasing autotrophic efficiency. Carboxysomes improve the efficiency of RuBisCO dramatically because they concentrate CO_2 and exclude O_2 at the site of RuBisCO activity. Even with carboxysomes, RuBisCO is a relatively inefficient and sluggish enzyme and so cells performing the Calvin cycle must contain very large amounts of RuBisCO protein. As a result, RuBisCO is thought to be the single most abundant protein on the Earth.

The evolutionary origins of the Calvin cycle remain unclear, but the low affinity for CO_2 and high sensitivity to O_2 of its key enzyme, RuBisCO, indicates that the cycle originated prior to the Great Oxidation Event (◀ Section 13.2). Carboxysomes were unnecessary at that time because the Earth's atmosphere had much higher levels of CO_2 and lower levels of O_2 than it has today. Indeed, carboxysomes are completely absent from chloroplasts and this infers that the cyanobacterial ancestor of chloroplasts possessed the Calvin cycle but lacked carboxysomes. Molecular sequence analysis indicates that carboxysomes originated in nonphototrophic bacteria and were acquired by cyanobacteria during horizontal gene transfer events well after the origin of chloroplasts. There is intense interest in discovering a way to bioengineer carboxysomes into the chloroplasts of plants because such a modification would increase photosynthetic efficiency and plant growth.

Although the Calvin cycle is the most widespread and important pathway of CO_2 fixation in the biosphere, many autotrophic *Bacteria* and *Archaea* employ alternative pathways for fixing CO_2 .

The Reverse Citric Acid Cycle

Not all phototrophic organisms rely on the Calvin cycle for CO_2 fixation. The **reverse citric acid cycle** (also called the *reductive tri-carboxylic acid cycle* or *rTCA cycle*) is a pathway of CO_2 fixation used

Jessup M. Shively

Figure 14.3 Crystalline Calvin cycle enzymes: Carboxysomes. Electron micrograph of carboxysomes purified from the chemolithotrophic sulfur oxidizer *Halothiobacillus neapolitanus*. The structures are about 100 nm in diameter. Carboxysomes are present in a wide variety of obligately autotrophic aerobic *Bacteria*.

Figure 14.4 Reverse citric acid cycle. The reverse citric acid cycle is the mechanism of CO₂ fixation in green sulfur bacteria and many microaerophilic and anaerobic chemolithotrophs. Fd_{red} indicates carboxylation reactions requiring reduced ferredoxin. Starting from oxaloacetate, each turn of the cycle results in three molecules of CO₂ being incorporated and pyruvate as the product. Pyruvate is a key metabolite that can feed directly into the glycolytic pathway, generating sugars and other important biosynthetic intermediates.

by green sulfur bacteria such as *Chlorobium* (► Section 15.6). The rTCA cycle is also used by many anaerobic and microaerophilic chemolithotrophic *Bacteria*. In the rTCA cycle, CO₂ is reduced by a reversal of steps in the citric acid cycle (◄ Section 3.6; Figure 14.4). The rTCA cycle is more energy efficient than the Calvin cycle, requiring 24 H (that come from 4 NADH, 2 NADPH, 2 FADH, and 4 Fd_{red}) but only 10 ATP to fix 6 CO₂ into one molecule of fructose 1,6-bisphosphate. [Note that in the cycle (Figure 14.4), although only four ATP are shown, one ATP is converted into AMP instead of ADP and hence 5 ATP equivalents are consumed per glyceraldehyde 3-P formed. Two molecules of glyceraldehyde 3-P can be converted into fructose 1,6-bisphosphate by reversal of the aldolase step of glycolysis (◄ Figure 3.11).]

As the name implies, most of the reactions of the reverse citric acid cycle are catalyzed by reverse reactions of enzymes of the citric acid cycle. However, the cycle also requires the activity of several unique enzymes. These include in particular the enzymes α -ketoglutarate synthase and pyruvate synthase, which catalyze the reductive fixation of CO₂ using electrons supplied by Fd_{red}. In green sulfur bacteria, Fd_{red} is produced in the light reactions of photosynthesis (see Figure 14.16), whereas chemolithotrophic bacteria must produce it from reverse electron transport or flavin-based electron bifurcation (Figure 14.2). The two ferredoxin-linked reductions are (1) the carboxylation of succinyl-CoA to α -ketoglutarate, and (2) the carboxylation of acetyl-CoA to pyruvate (Figure 14.4). The rTCA cycle also replaces the enzyme *citrate synthase* from the citric acid cycle (◄ Figure 3.12) with the enzyme *citrate lyase* (an ATP-dependent enzyme that cleaves citrate into acetyl-CoA and oxaloacetate), and the enzyme *succinate dehydrogenase* from the citric acid cycle by the FADH-linked *fumarate reductase* (an enzyme that forms succinate from fumarate) in the reverse cycle (Figure 14.4).

Other Pathways of CO₂ Fixation

In addition to the Calvin cycle and the rTCA cycle, at least four other pathways of CO₂ fixation are known, and we consider them here only briefly. Green nonsulfur bacteria such as *Chloroflexus* (► Section 15.7) grow autotrophically with either H₂ or H₂S as electron donor. However, neither the Calvin cycle nor the reverse citric acid cycle operates in this organism. Instead, two molecules of CO₂ are reduced to glyoxylate by the *3-hydroxypropionate bi-cycle*. This cycle is so named because hydroxypropionate, a three-carbon compound, is a key intermediate and because it couples two cycles to ultimately yield pyruvate, which can then be converted into glyceraldehyde 3-P as in the rTCA cycle (Figure 14.4).

Archaea appear to lack the Calvin and rTCA cycles as well as the 3-hydroxypropionate bi-cycle. Instead, many chemolithotrophic *Archaea* use either the *3-hydroxypropionate/4-hydroxybutyrate cycle* or the *dicarboxylate/4-hydroxybutyrate cycle*. Each of these autotrophic cycles includes two connected pathways in which bicarbonate and/or CO₂ is reduced to acetyl-CoA, and they are named for their key intermediates, 3-hydroxypropionate, 4-hydroxybutyrate, and C₄ dicarboxylic acids.
